# CHAPTER 4

Sedimentary changes during the last ~2500 years have been reconstructed from cored sedimentary records from the deltaic floodplain of the Lower Tagus Valley and the Tagus mudbelt on the continental shelf offshore Lisbon. We used a multi-proxy approach consisting of sedimentology, grainsize, pollen data and magnetic susceptibility. In the floodplain grainsize coarsened and sedimentation rate and magnetic susceptibility increased during the late Holocene due to an increased flooding frequency and/or intensity. On the Tagus shelf the mudbelt grainsize fined, together with a higher sedimentation rate and increased magnetic susceptibility. The fining grainsize is explained by an increased suspended sediment flux towards the shelf and subdued winnowing. Floodplain and shelf records were correlated by radiocarbon dating and changes in sediment characteristics. We identified four depositional phases (~2300/~1600/~1100/~670 cal BP) on the floodplain and the shelf. These are tentatively explained by land-use changes in the Tagus catchment.

## Late Holocene sedimentary changes in floodplain and shelf environments of the Tagus River (Portugal)

**Based on:** Vis, G.-J., Kasse, C., Kroon, D., Jung, S., Zuur, H. and Prick, A., Late Holocene sedimentary changes in floodplain and shelf environments of the Tagus River (Portugal). *Submitted to a peer-reviewed journal.*

## 4.1 INTRODUCTION

Mankind has a profound impact on system earth and is able to reshape natural environmental systems, thereby affecting their stability. Past changes in land-use and forest cover have caused significant changes in river discharge, soil erosion and deposition in delta's and offshore environments (e.g. Bosch and Hewlett, 1982; Hornbeck *et al.*, 1993; Sahin and Hall, 1996; Lang *et al.*, 2003; Andréassian, 2004; Jordan *et al.*, 2005; Ward *et al.*, 2008).

On the Iberian Peninsula the effect of soil erosion on fluvial sediment loads and deposition has been felt during the last ~2000 years. The sediment

**Figure 4.1 |** Location map of the Lower Tagus Valley. The inset map (A) shows the Tagus catchment and study area on the Iberian Peninsula, Digital Elevation Data from Jarvis *et al.* (2006). 1: Mesozoic Spanish Cordillera; 2: Spanish Tertiary Sedimentary Tagus Basin; 3: Palaeozoic Hesperian Massif; 4: Lower Tagus Basin (LTB). The main map (B) shows the location of the terrestrial and marine cores.

load of the Ebro River in northeast Spain increased fourfold since ~700 cal BP due to catchment deforestation, which caused increased delta shoreline progradation (Guillén and Palanques, 1997). Chester and James (1991) argued that the temporal correlations between phases of intensive agriculture, deforestation and valley alluviation during the last two millennia in south Portugal were most likely the result of anthropogenic forcing. According to Thorndycraft and Benito (2006a) slackwater deposits from the last 1300 years in Spain, reflect increased human impact on the landscape. For the Muge River, a Lower Tagus tributary, evidence of increased overbank sedimentation since ~2150 cal BP, has been attributed to progressive human impact on catchment vegetation (Van der Schriek *et al.*, 2007a, b).

Studies conducted on seafloor sedimentary sequences along continental margins, mainly focus on palaeoceanography, while a minority addresses the forcing factors controlling terrestrial material transport to the ocean. Human impact was identified on the Eel and California shelves, where accumulation rates increased dramatically during the past centuries due to land use changes (Leithold *et al.*, 2005; Sommerfield and Wheatcroft, 2007). On the Adriatic Sea floor accelerated sedimentation and increased input of terrigenous material were caused by widespread deforestation and cultivation (Oldfield *et al.*, 2003). Recent (<2000 years) deposition of fine-grained sediments on the Gironde shelf has been linked to increased sediment supply resulting from soil erosion in the catchment (Lesueur *et al.*, 1996).

The studies mentioned above have in common that they view the sedimentary system either from a “land-based” perspective or from an “ocean-based” perspective. Thus it is timely to improve our understanding of sedimentation of the complete fluvial-estuarine-shelf depositional system. Therefore this chapter aims to: 1) correlate fluvial and marine sedimentary records, 2) identify depositional phases in both environments, and 3) explore the external forcing mechanisms (climate, man) in both records. Because the sedimentary records are located at the downstream end of the Tagus depositional system, they contain a “smoothed” signal of complex processes like sediment erosion, flux, storage and winnowing.

## Fluvial setting

The Tagus River has a length of ~1000 km and a catchment area of 80,630 km<sup>2</sup> (Bettencourt and Ramos, 2003; Le Pera and Arribas, 2004). The Tagus originates at an elevation of about 1600 m in eastern Spain and flows westwards (Fig. 4.1) finally entering the NNE-SSW oriented Lower Tagus Basin. Presently, the main soil types—in FAO UNESCO terminology—in the catchment are Cambisols, Regosols, Podzols and Luvisols with typical depths-to-rock of <80 cm. Land use is dominated by arable land, forest, extensive pastoral forest

parks (“dehesa”) and olive orchards (European Soil Portal, 2008). The average discharge of the regulated Tagus River near its mouth is 400 m<sup>3</sup>/s. The river is characterised by extreme seasonal and annual variability with peak discharges more than 30 times the average discharge (Benito *et al.*, 2003a; Bettencourt and Ramos, 2003). The present-day Lower Tagus floodplain (Fig. 4.1) is 5–10 km wide and ~85 km long, has an elevation of ~22 m near Golegã in the north and ~2 m near Vila Franca de Xira in the south, with an average gradient of ~24 cm/km. South of Vila Franca de Xira the river enters a large central basin.

### Estuarine setting

The central basin south of Vila Franca de Xira is characterised by a semi-diurnal mesotidal regime with floods typically lasting an hour longer than ebbs, making it an ebb-dominated tide. The mean tidal amplitude in the central basin is 1.5 m at neap tide and 4 m at spring tide (Portela and Neves, 1994; Bettencourt and Ramos, 2003). The average water depth in the central basin is 5 m (Fig. 4.1) and the basin floor is dominated by silt and clay; sand is only present in the narrow tidal inlet channel south of Lisbon (Portela and Neves, 1994). This up to 40 m deep channel connects the basin to the Atlantic Ocean and ebb flow speeds of 2–3 m/s are reached (Bettencourt and Ramos, 2003). Due to its sheltered position, waves play a very minor role within the central basin, where only a small fraction of the tidal energy reaches the fluvial domain (Fortunato *et al.*, 1999).

### Marine setting

The Atlantic Ocean west of Lisbon consists of a passive continental margin with a narrow continental shelf (<30 km). The Atlantic coast off Portugal is affected by a high-energy wave regime with winter wave heights of up to 10 m (Instituto-Hidrográfico-Portugal, 2008). The Atlantic surface waters (< ~100 m) are dominated by the Portugal Current System (PCS), consisting of a slow southward current in the open ocean and a fast, seasonally reversing coastal current (Fiúza, 1983; Arhan *et al.*, 1994; Peliz and Fiúza, 1999). During late spring and summer, the Azores high-pressure system is located over the central North Atlantic and the Greenland low-pressure system is weak, causing prevalent northerly and north-westerly winds, leading to a southward coastal PCS and generating coastal upwelling (Fiúza, 1983; Haynes and Barton, 1990; Peliz and Fiúza, 1999). Autumn and winter are characterised by a northward flowing coastal PCS, because the Açores high-pressure system is located over the southern North Atlantic and the deep Greenland low-pressure system causes strong winds from the southwest, triggering coastal downwelling (Frouin *et al.*, 1990; Haynes and Barton, 1990).

## 4.2 METHODS

### Terrestrial and marine cores

We selected three cores (0501.016, .025 and .029) from a dataset of 126 cores and 9 cross sections from the Lower Tagus Valley (Fig. 4.1, Table 4.1) which best recorded depositional phases based on the distribution of facies units and palaeogeography (Chapters 2 and 3). These cores were used for a multi-proxy approach by analysing grainsize, loss-on-ignition (LOI), radiocarbon age, pollen content and magnetic susceptibility (MS). Two nearby cores (0501.401 and 0601.002) were used for additional radiocarbon dates, which were projected to cores 0501.016 and 0501.025 respectively. Coring locations (Table 4.1) were measured using a Garmin GPS-12 receiver (horizontal resolution ~5 m). The cores were manually recovered using Edelman augers for sediment above the groundwater table and the gauge for sediment below the groundwater table. The sediments were described in the field at 10 cm intervals following the method explained in Berendsen and Stouthamer (2001) and lithology was converted to USDA terminology. The elevation of corings 0501.016, .025 and .401 (Fig. 4.1) relative to ordnance datum was measured using Trimble DGPS equipment (vertical resolution ~5 mm) and the elevation of corings 0501.029 and 0601.002 was taken from topographic maps (IgeoE, Portugal).

The terrestrial cores are located in distal overbank settings where fine-grained sediment is deposited from suspended load of overbank flood water. A period with such events is registered in the sedimentary record as a fine-grained sediment layer, reflecting multiple overbank floods. In low-lying areas which aggrade rapidly, like the Lower Tagus Valley, it is generally assumed that important hiatuses are absent at lithological boundaries (Törnqvist and Van Dijk, 1993). The cross sections indicate that the depositional phases identified in the cores have a large aerial extent in the Lower Tagus Valley and therefore most likely reflect deposition due to external forcing.

Nine marine cores from the Tagus mudbelt on the continental shelf offshore Lisbon were used (Fig. 4.1, Table 4.1). Of these cores, one piston core (GeoB-8903-1) was used for a multi-proxy approach using grainsize, radiocarbon age and MS. The other cores were used to reconstruct the spatial sediment distribution using MS signals. Although local accumulation rates may be different, we assume a more or less even sediment accumulation on the mudbelt as a result of deposition from suspension from the Tagus outflow.

### Sample treatment

Grainsize was measured using a Fritsch A22 Laser Particle Sizer following the methods described by Konert and Vandenberghe (1997), including removal of organic matter and carbonates. The marine core contained very little opal as

was confirmed by visual inspection using a microscope, so no additional measures to remove this were taken. Grainsize of the terrestrial cores was measured at 5–10 cm intervals, marine core GeoB-8903-1 was measured at a 1 cm interval. Grainsize statistics (mean and D90 = grainsize at which 90 % is finer) were calculated using the program GRADISTAT (Blott and Pye, 2001). Matlab 7.4.1 software was used to calculate equal-depth intervals for the contour plots which were visualised using Surfer 8 software.

A LECO TGA-601 was used to determine loss-on-ignition of 110 dried and grounded samples of approximately 2 g of core 0501.029 (Fig. 4.2) resulting in “classic”LOI<sub>550</sub>. Due to heating, structural water and -OH bounds in the (clay) minerals were lost as well, causing a slight overestimation of the LOI.

Pollen samples were prepared according to Faegri and Iversen (1975); clastic material was removed using a sodium polytungstate heavy liquid separation. Samples were counted at the Friedrich-Schiller University in Jena (Germany). The percentage of anthropogenic indicator pollen was calculated based on the regional pollen sum.

## Radiocarbon dating

A set of 26 radiocarbon dates was used to construct the chronological framework (Table 4.2). The 9 terrestrial radiocarbon samples consisted of terrestrial botanical macrofossils or bulk samples. Botanical macrofossil samples (from generally 1 cm thick sediment slices) were boiled with sodium pyrophosphate and washed through a 125 µm sieve. Macrofossils were picked from the residue and determined at VU University Amsterdam. The terrestrial radiocarbon ages were calibrated using the program OxCal v3.10 (Bronk Ramsey, 2005) using the IntCal04 terrestrial age calibration data from Reimer *et al.* (2004).

The 17 marine radiocarbon dates were based on planktonic foraminifera and marine shells and molluscs. The marine radiocarbon ages were calibrated using the program CALIB v5.0 (Stuiver and Reimer, 1993; Stuiver *et al.*, 2005) and the Marine04 age calibration data from Hughen *et al.* (2004). The marine calibration incorporates a time-dependent global ocean reservoir correction of about 400 years. Abrantes *et al.* (2005) proved that this is a good estimate for marine material off Portugal for the last ~110 years, however, older dated material may have been affected by different conditions. Therefore and to correct for local variations, the difference in reservoir age of the study area and the global ocean was determined ( $\Delta R = 262 \pm 164$  y) using the marine reservoir correction database by Stuiver and Braziunas (1993). All mentioned radiocarbon dates are expressed as calibrated calendar ages (cal BP) with age spans at the 2σ range.

## Magnetic Susceptibility

Magnetic susceptibility measurements were volume-based low field ( $\kappa$ ) and measured using Multi Sensor Core Logging 7.6 (MSCL) equipment (Geotek Ltd.), mounted with an MS2C Bartington magnetic susceptibility meter with loop sensor. Cores were measured every centimetre (every 0.5 cm for 0501.029) during 10 s. The upper 4 m of cores 0501.016 and .025 and the upper 2 m of core 0501.029 were recovered using an Edelman auger; in that case, each data point represents the average MS of a ten centimetre interval.

Marine core D13902 was measured at the Southampton Oceanography Centre (Abrantes *et al.*, 2008). All other marine cores were measured at the Research Centre Ocean Margins (RCOM) in Bremen, Germany (Monteiro *et al.*, 2002; Segl *et al.*, 2004; Labeyrie and Turon, 2005a, b; Segl and Alt-Epping, 2005a, b).

## 4.3 RESULTS

### Terrestrial cores

#### *Core 0501.029 (Fig. 4.2)*

This core was recovered in nature reserve Paul do Boquilobo (Fig. 4.1). The total core covers the last ~7000 years and measures 12 m, of which the upper 6 m are used here. The Holocene Tagus channel was always located ~4 km northwest from this site, implying continuous low-energy backswamp conditions (Chapter 3); clay units reflect periods of more frequent Tagus flooding.

The lithological column (Fig. 4.2a) shows at the base calcareous gyttja (6–4.7 m below surface) deposited between 3390–3210 cal BP (UtC-14747) and ~2200 cal BP at a rate of ~1.2 mm/y. The overlying peat interval (4.7–3.1 m) with LOI values up to 60 % (Fig. 4.2e) accumulated at a rate of ~1.3 mm/y until 1180–960 cal BP (UtC-14749) and 1060–790 cal BP (UtC-14750), when peat growth abruptly ended due to the onset of clay deposition at 3.1 m depth. This upper clay layer was deposited at a higher sedimentation rate of ~3.1 mm/y, contains plant roots and has low LOI values (~8 %). The onset of sedimentation coincides with a MS peak of  $230 \times 10^{-5}$  SI at 3.1 m depth (Fig. 4.2b), just above a charcoal-rich layer—burnt soil is known to give high MS values (Thompson *et al.*, 1980; Weston, 2002). Generally, MS increased strongly from ~3.4 m upwards, coinciding with decreasing LOI values, marking the transition from peat-dominated to clay-dominated deposition. Above the MS peak at 3.1 m depth, MS values remain relatively high, fluctuating around an average of  $\sim 7 \cdot 10^{-5}$  SI. The interval below 3.4 m depth holds virtually no MS signal.

**Table 4.2 |** Radiocarbon dates from the Lower Tagus Valley and the Tagus mudbelt. Coordinates (X-Y) in European Datum 1950/UTM Zone 29N.

Synchronous with the change from peat to clay-dominated deposition and the increase of MS, the input of pollen indicating anthropogenic impact increased (*Chenopodiaceae*, *Artemisia*, *Campanulaceae*, *Echium*-type, *Urtica*, *Xanthium*-type, *Cannabis/Humulus*, *Olea europaea*, *Cerealina*, *Juglans*, *Polygonum aviculare* and *Brassicaceae*) (Fig. 4.2g), coeval with a decline of tree vegetation. The mean grainsize shows minor coarsening from 3.1 m upwards, especially expressed in the D90 and grainsize distribution (Fig. 4.2c, d, h).

#### Core 0501.016 (Fig. 4.3)

Core 0501.016 was recovered ~1.5 km northwest of the present Tagus channel in a floodplain/distal levee setting (Chapter 3), thus recording changes in Tagus proximal overbank sedimentation (Fig. 4.1). The sediments of the 23 m long core accumulated since ~9000 cal BP; for this study the upper 7.5 m were used (Fig. 4.3). Chronology is based on three projected radiocarbon dates from coring SEV (Azevêdo *et al.*, 2006a), located 900 m to the northwest (0501.401, Fig. 4.1).

The basal part of the lithological column (7.5-1.4 m) shows an alternation of silt and clay layers with minor mean grainsize changes (Fig. 4.3c). This lower part was deposited at a rate of ~2.2 mm/y between ~3550 cal BP and ~816 cal BP. The sandy interval around 6.5 m depth is attributed to a large flood (Fig. 4.3d, f). The upper 1.4 m, deposited after ~816 cal BP at a rate of ~1.8 mm/y, consist of very fine to medium sand in a coarsening-upward unit. The coarsening is well expressed in the D90, which reaches values up to ~450  $\mu\text{m}$  and the grainsize distribution is strongly skewed and somewhat bimodal with a large medium sand and a minor silt peak, implying levee-type sedimentation (Fig. 4.3f).

In the basal 4.5 m of the core, clay intervals contain higher MS values than silt intervals, suggesting a relationship between finer grainsize and magnetic-particle content (Fig. 4.3a, b) (cf. Oldfield *et al.*, 1985). Around 4.7 m depth a MS peak occurs *within* the clay interval (Fig. 4.3b) and between 3 and 2 m depth MS rises *within* clay layers, suggesting increased magnetic-particle concentration. From ~2 m depth upwards, the MS signal reaches unprecedented values around  $15 \cdot 10^{-5}$  SI and both the silt and sand intervals show high MS values.

#### Core 0501.025 (Fig. 4.4)

This southernmost core was recovered ~300 m east of the Tagus channel (Fig. 4.1) and holds a record of overbank and levee sedimentation (Chapter 3). The core measures ~13 m deposited since ~8000 cal BP, of which the upper 6.4 m were used for this study. Using three radiocarbon dates, a chronology was constructed. The upper two dates were projected to this core from core 0601.002

which is located ~350 m to the east (Chapter 3, Fig. 3.5), based on the stratigraphic position just above a ripened soil (UtC-14745) and on a distinctive organic soil level which was found in both cores (UtC-14744).

The lithological column shows a basal silty clay interval (6.4-3.5 m) deposited at a rate of 0.7 mm/y. A level of soil ripening around 5.5 m depth (Fig. 4.4a) marks the top of tidal marsh deposits, which were deposited here between ~7000 and ~5000 cal BP (Chapter 3). The overlying silty clay (3.5-0 m) resulted from Tagus overbank sedimentation at a rate of 3.5 mm/y (Fig. 4.4d). In this interval charcoal fragments and two organic soil levels were found. The upper soil level was best-developed and dated at 1610-1410 cal BP (UtC-14744). The coarsening-upward unit and the sand layers around 2.5 m depth match a levee-type environment, which is supported by a bimodal grainsize distribution with a silt and a fine sand population between 2.5 and 0.5 m depth (Fig. 4.4f). Both the mean and D90 grainsize (Fig. 4.4 c, d) show a fining-upward trend from ~0.5 m upwards.

The MS signal is low (noise) in the basal clayey 2 m of the core and subsequently rises to a peak of  $\sim 20 \cdot 10^{-5}$  SI around 4.2 m depth within the clay interval (Fig. 4.4b). Around 3.5 m depth, MS rises to  $\sim 33 \cdot 10^{-5}$  SI, simultaneously with coarsening lithology as visible in the D90 curve (Fig. 4.4d). From 2.5 m depth upwards, MS slowly decreases to  $\sim 15 \cdot 10^{-5}$  SI while lithology coarsens further; possibly because of less fine-grained magnetic particles in the sandy sediment.

## Interpretation of terrestrial cores

In the upper 2-3 m of all cores the grainsize coarsens upwards, implying an increased flooding frequency and/or intensity. Sedimentation rates increase up to threefold in this interval. Although compaction of the organic-rich deposits in the lower part of core 0501.029 created syn-sedimentary accommodation space, the sudden change from peat accumulation to clay deposition at 3.1 m depth must have been controlled by a sudden increase of Tagus overbank sedimentation. Increased overbank sedimentation is corroborated by a tripled sedimentation rate, low values of LOI, the coarsening-upward grainsize and by 2-3 m of overbank deposits covering a ~850 years old floodplain soil in the Golegã cross section north of core 0501.029 (Chapter 3, Fig. 3.2). Furthermore, the regional anthropogenic pollen content increases strongly in the upper 3 m of this core and simultaneously there is a strong increase of the MS signal in the upper part of the other cores.

The sedimentary and ecological changes mentioned above strongly suggest increased human impact on floodplain sedimentation. The strong increase of MS can be explained by the increased supply of magnetic particles from eroded soils and sediments (cf. Thompson *et al.*, 1980; Dearing *et al.*, 1986;

Faleh *et al.*, 2005). Burning possibly enhanced in-situ soil MS in the catchment (Thompson *et al.*, 1980; Weston, 2002), as supported by the increased amount of charcoal in the younger (<500 yr) levee and fluvial channel deposits.

The lower 6 m in core 0501.016 (Fig. 4.3) and the lower 3 m in core 0501.025 (Fig. 4.4) have a relatively stable grainsize distribution, apart from some sand intervals in core 0501.016. Although the MS signals are equally stable in both cores, around 4.5 m depth a MS peak is present within a uniform clay layer. This suggests a larger supply of magnetic particles to both sites (cf. Oldfield *et al.*, 1985). Fine-grained (< 0.03  $\mu\text{m}$ ) magnetic particles in palaeosols are responsible for increased in-situ MS values (Oldfield *et al.*, 1985; Maher and Thompson, 1991; Zheng *et al.*, 1991; Maher and Thompson, 1992). Furthermore, widely occurring Cambic Bw horizons in Cambisols in the Tagus catchment (European Soil Portal, 2008) show relatively high MS values in the upper 20-50 cm because of weathering and pedogenic  $\text{Fe}_2\text{O}_3$  formation (FitzPatrick, 1983; Hanesch and Scholger, 2005). Therefore, the MS peaks in both cores may indicate that fine grained soil material was eroded from the catchment (cf. Faleh *et al.*, 2005) and at least partly deposited in the Lower Tagus Valley floodplain.

## Marine core

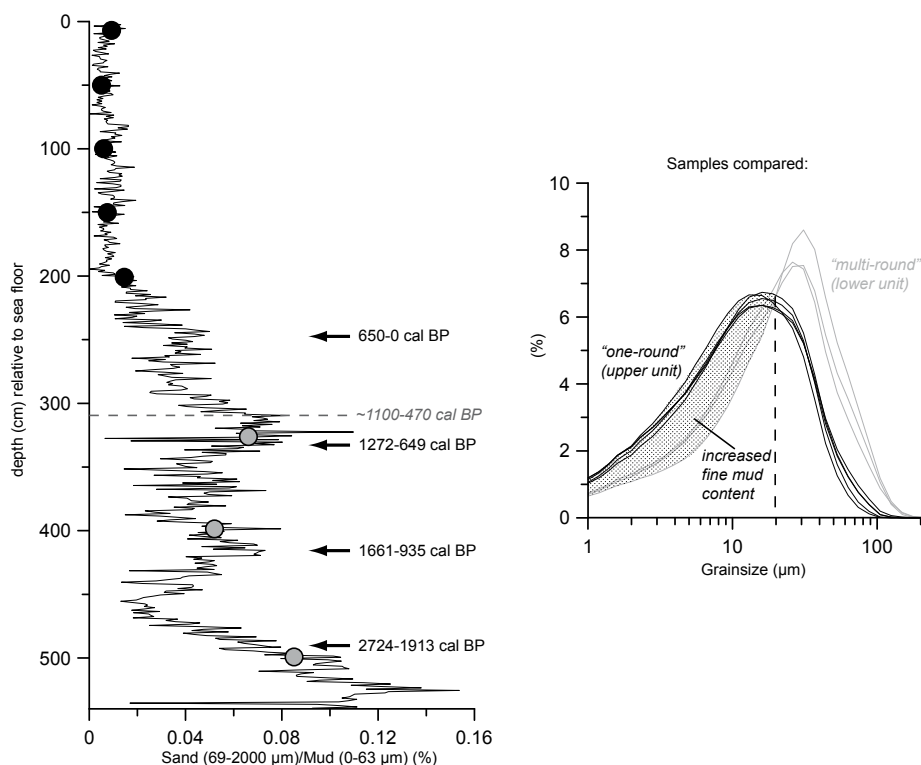

### Core GeoB-8903-1 (Figs. 4.5 and 4.6)

Recovered from the Tagus mudbelt at 102 m water depth, core GeoB-8903-1 (Figs. 4.1 and 4.5) measures 5.4 m and is dominated by silt and clay. Using 10 AMS radiocarbon dates based on planktonic foraminifera, a chronology was established. The upper 2 m are constrained by six dates, which all lie within the last ~400 years cal BP ( $2\sigma$ ) (Table 4.2). Four C-14 ages between 0.65 and 1.98 m depth ( $735 \pm 55$  BP (KIA 30890),  $760 \pm 25$  BP (KIA 28967),  $685 \pm 30$  BP (KIA 28968) and  $760 \pm 45$  BP (KIA 27064)) have overlapping  $1\sigma$  standard deviations, making them virtually coeval. The similar ages of the upper six radiocarbon dates may be the result of the tsunami of 1755 AD. However, in core GeoB-8903-1 sedimentary characteristics pointing to erosion/deposition caused by a tsunami were not identified (Alt-Epping *et al.*, 2009).

The lithological column (Fig. 4.5a) shows a silt-dominated basal interval (5.4-3.1 m depth), which was deposited at a rate of ~1.2 mm/y since about 2724-1913 cal BP (KIA 27320). Shortly after that date, between 5 and 4.5 m depth, the MS signal shows the first peak of  $\sim 6 \cdot 10^{-5}$  SI, and a temporal grainsize fining (Fig. 4.5b-d). Between 4.5 and 3.1 m depth, grainsize mean and D90 fluctuate without showing a trend (Fig. 4.5f). The upper 3.1 m accumulated at a rate of ~3.9 mm/y since ~1100-470 cal BP (based on linear interpolation from KIA 27066 to KIA 27065). Between 3.1 and 2 m depth the mean and D90 grainsize fine upwards until 428-0 cal BP (KIA 27064)

**Figure 4.5** | Marine core GeoB-8903-1 from the Tagus mudbelt; a) lithological column; b) magnetic susceptibility; c) mean grainsize; d) D90 grainsize; e) radiocarbon age and sedimentation rate; f) grainsize distribution.

**Figure 4.6** | Sand/mud ratio for marine core GeoB-8903-1 (left) and selected grain-size frequency diagrams from circled intervals (right). An upcore increase of fine mud content is visible in both the sand/mud ratio and the grain-size frequency diagrams, with the transition around 1100-470 cal BP.

and between 3.1 and 2.7 m depth the MS shows a peak with values around  $10 \cdot 10^{-5}$  SI in a finer grained layer. Above that peak, MS rises rapidly to values around  $33 \cdot 10^{-5}$  SI at ~2 m depth simultaneously with further grainsize fining. The upper 2 m are finest grained and very uniform and homogeneous with continuously high MS values (Fig. 4.5b, c). The observed correspondence between the major MS patterns and the grainsize changes suggests that the clay-dominated intervals contain most magnetic particles. This is corroborated by XRF-Fe measurements by Abrantes *et al.* (2008) and by an excellent correlation ( $R^2=0.9$ ) between MS and the finest grainsize end-member in the core (EM1, average grainsize 6 µm, Alt-Epping *et al.*, 2009).

The MS changes of this marine core resemble the MS signal of the floodplain cores. However, the coeval grainsize changes are the opposite from the changes on land. Grainsize shows a fining-upward trend offshore, with overall decreasing sand (from 10 to 0.5 %) and silt (from 70 to 55 %) concentrations in favour of clay (from 20 to 40 %) concentrations (Fig. 4.5f). This offshore grainsize fining can be explained by mixing processes occurring in the Tagus estuary and sedimentary processes taking place on the Tagus shelf.

Suspended sediments in the Tagus estuary were thoroughly mixed due to tidal currents and the turbidity maximum (Vale and Sundby, 1987; Barros, 1996). Subsequent transport to the shelf occurred as surficial and bottom nepheloid layers (Jouanneau *et al.*, 1998), where further mixing took place (McCave *et al.*, 1995). The strong mixing of suspended sediment during offshore transport, limits reasons to assume that the grainsize change in core GeoB-8903-1 reflects an altered composition of the source of suspended sediment.

To examine sedimentary processes on the shelf, we compared individual grainsize distributions from eight levels in core GeoB-8903-1 (Fig. 4.6). A distinct change was observed between 3.2 and 2.0 m depth. The grainsize distributions of the three deepest samples have a higher concentration in the fraction 20–200  $\mu\text{m}$ , whereas the upper five samples have a higher concentration in the fraction 0–20  $\mu\text{m}$ . This implies an upward increase in the <20  $\mu\text{m}$  fraction (cf. Alt-Epping *et al.*, 2009). The grainsize distributions of the three deepest samples closely resemble “multi-round” distributions (Kranck *et al.*, 1996b). These are sediments which have been resuspended and settled causing further sorting after initial deposition. Each resuspension event (“round”) removed the fine-grained particles and changed the grainsize distribution, thereby steepening the fine-grained limb of the grainsize distribution. The five upper grainsize distributions closely resemble “one-round” distributions (Kranck *et al.*, 1996a), which result from settling from suspension without subsequent reworking. This means that the grainsize distribution of the upper five samples resembles the distribution of the parent suspension. Therefore, these samples have experienced considerably less postdepositional sorting (winnowing) than the lower three samples.

The decreased effect of winnowing in the upper  $\sim 3.1$  m resulted in preservation of the fine mud fraction (Fig. 4.6). Winnowing apparently was less effective in the upper interval, suggesting changed boundary conditions. Either winnowing occurred less than before, or the relative effect of winnowing decreased due to rapid sedimentation resulting from an increased suspended sediment flux. The latter explanation is supported by a threefold increase in sedimentation rate for the upper  $\sim 3.1$  m. The increased suspended sediment flux also has a hydrodynamic meaning, since silt in the 10–63  $\mu\text{m}$  fraction is deposited as sortable single grains, whereas silt and clay in the 0–10  $\mu\text{m}$  fraction demonstrate cohesive behaviour of flocculated aggregates (McCave *et al.*, 1995). An increased suspended sediment concentration also led to more flocculation and a larger depositional flux of sediment in the 0–10  $\mu\text{m}$  fraction. When silt and clay in the 0–10  $\mu\text{m}$  fraction reach the ocean floor, the cohesive sediment behaviour also hampers resuspension and sorting, making winnowing less effective as well.

## Land-sea correlation

To explain the large-scale depositional changes in the Tagus terrestrial and marine system we correlated the three floodplain records and the marine record presented above together with records from eight previously studied mudbelt cores (Fig. 4.7, Table 4.1). The latter cores were used to extrapolate the results from core GeoB-8903-1 to the entire Tagus mudbelt using radiocarbon dates and MS signals. Striking similarities in timing are visible between the floodplain and mudbelt cores, suggesting that deposition was controlled by external forcing.

The two oldest depositional phases correspond with modest grainsize fining in core GeoB-8903-1. They coincide with relatively small MS peaks in five cores across the mudbelt (Fig. 4.7, Nos. 1 and 2). Phase 1 has an age of 2724-1913 cal BP (KIA 27320, core GeoB-8903-1). Phase 2 has an average age of ~1600 cal BP, based on a date in core D13902 (1999-1733 cal BP, AAR-7210) and in core GeoB-8903-1 (1661-935 cal BP, KIA 27067).

Depositional phase 1 was identified in two terrestrial cores (0501.025 & .016) (Fig. 4.7, No. 1). In core 0501.025 a level just below this peak was dated at 4420-4100 cal BP (UtC-14745). This date is based on a bulk clay sample which may be contaminated with old carbon. Other studies have also found too old ages for bulk samples (up to 1500 years) due to old carbon in the depositional system (Colman *et al.*, 2002; Van der Schriek *et al.*, 2007b). The date of ~3086 cal BP in core 0501.016 is in agreement with the estimated age of ~2300 cal BP for depositional phase 1. Depositional phase 2 could not be identified in the terrestrial cores.

Clearly recognisable in all cores is depositional phase 3 (Fig. 4.7), which preludes the upper interval with high MS values (No. 4). The average age of depositional phase 3 is ~1100 cal BP, based on dates in marine cores D13902 (1568-1403 cal BP, AAR-7828) and GeoB-8903-1 (1272-649 cal BP, KIA 27066) and dates in terrestrial core 0501.029 (1060-790 cal BP, UtC-14749 and 1180-960 cal BP, UtC-14750). Grainsize changes are modest, showing some grainsize decrease offshore and a modest increase on land.

During depositional phase 4 grainsize strongly decreases offshore and increases onshore and sedimentation rates increase up to threefold. All cores show high MS values (Fig. 4.7, No. 4). Deposition of this upper interval starts ~670 cal BP, based on dates of 915-764 cal BP (KIA 23661), 772-653 cal BP (AAR-7207), 650-0 cal BP (KIA 27065) and 816 cal BP. Hiatuses and instantaneously deposited layers associated with the 1755 tsunami may be present in the upper 2-3 m of some marine cores (Abrantes *et al.*, 2008, Fig. 7). Because the grainsize decrease and MS increase at level No. 4 predates these hiatuses, a strong external forcing is assumed for this depositional phase. In the terrestrial cores, the relatively small fluctuations of MS in the upper interval (above No.

TERRESTRIAL CORES

MARINE CORES

3) can be related to grainsize changes, caused by levee progradation in the floodbasin environment.

## 4.4 DISCUSSION

### Value of magnetic susceptibility

Local formation or dissolution of magnetic particles may however hamper the interpretation of MS records. Under poorly drained or prolonged water-logged reducing conditions, ferric iron (Fe(III)) changes to the more soluble ferrous iron (Fe(II)), which is accompanied by loss of reddish and brownish soil colours in favour of a grey colour (Weston, 2002; Grimley and Arruda, 2007). Despite the grey colour of the sediment and reducing conditions below 1 m depth in the waterlogged core 0501.029, the MS values are high (Fig. 4.2b), implying that the magnetic particles were not dissolved and removed or formed in-situ and therefore they were transported to the site and deposited with the sediment. The other two terrestrial cores were taken from dry floodplain sites with reducing conditions at 6-7 m below the surface (Figs. 4.3 and 4.4) and therefore they were not affected much by dissolution of magnetic particles. Although the floodplain soils are young and immature and situated in a dynamic environment, formation of in-situ magnetic particles through pedogenesis may have occurred. However, the major MS changes in these two terrestrial cores occur in homogeneous, fully oxidized floodplain sediments far above the groundwater level.

In the marine environment formation of autochthonous biogenic magnetite and the magnetic sulphide greigite may have complicated the MS signal. Greigite can form at or near the sediment/water interface in a decade or less in the marine realm (Oldfield *et al.*, 2003). However, in the marine cores the striking similarity of the MS signals despite varying sediment layer thicknesses, indicates that biogenic magnetite and greigite formation was of minor importance.

Bulk density changes may have occurred due to post-depositional compaction. However, no correction was made for dry bulk density because the well oxygenated clastic fluvial sediments have not experienced much compaction. Offshore, the sediments are much softer and experienced more compaction than on land. The upper metres of the marine cores consist of very soft sediment. In case of a constant supply of magnetic particles, an increasing

---

**Figure 4.7** | Land-sea correlation of 9 marine cores and 3 terrestrial cores. The cores indicated with (\*) originate from this study. Four phases were distinguished: 1) ~2300 cal BP; 2) ~1600 cal BP; 3) 1100 cal BP and 4) since ~670 cal BP. Italic ages are interpreted values; see text for explanation. Merging of records of cores PO287-26B and D13902, and hiatuses are based on Abrantes *et al.* (2008).

MS signal is expected with depth, because the upper lower-density sediment contains fewer particles. Nonetheless, the soft upper sediments contain the highest MS values, which confirms a higher supply of magnetic particles to the shelf.

Although volume-based magnetic susceptibility is the most basic magnetic susceptibility measurement, the results of this study suggest its applicability for correlation of deposits in conjunction with other sedimentological data (grainsize, LOI, pollen, radiocarbon ages). The similarity of magnetic susceptibility patterns and their timing in the studied cores shows that volume-based magnetic susceptibility can be used as a tool to correlate terrestrial and marine records.

### Climate change

The last 2500 years have experienced climatic changes like the Medieval Warm Period (900-1200 AD/1050-750 cal BP) and the Little Ice Age (1550-1900 AD/400-50 cal BP). In addition, during the 20th century Tagus winter discharge was largely controlled by the North Atlantic Oscillation, a relationship which probably also existed during previous periods of the Holocene (Trigo *et al.*, 2004). Although these climate changes have occurred, their impact on the sedimentary records is unclear. Furthermore, the major climate change from a humid to a drier climate around 5000 cal BP was not recognised in the fluvial records of the Lower Tagus Valley (Chapter 3). On the other hand, the limited chronological resolution of our cores hampers identification of short-term climatic changes. Recently it has been shown for the temperate-climate Meuse River that increased mean annual discharge and frequency of high-flow events can be ascribed to land use changes (mainly deforestation), while the effects of climatic change are insignificant (Ward *et al.*, 2008).

Since land-use changes during the last few thousand years in the Tagus catchment may have caused increased runoff, offshore proxy records should be interpreted with caution. For instance, indicators of increased freshwater discharge in the marine realm do not necessarily reflect increased *precipitation* on the continent but may reflect increased runoff and discharge due to the absence of the buffering effect of natural vegetation.

Abrantes *et al.* (2005) and Lebreiro *et al.* (2006) interpreted a larger mean grainsize and low MS values during the Medieval Warm Period in mud-belt cores PO287-26B and D13902 as climate-related decreased runoff. Increased fine-grained deposition, high MS values and the presence of freshwater diatoms in marine sediments during the Little Ice Age, have been interpreted as increased rainfall and a larger Tagus discharge. The MS pattern of these cores closely matches the MS patterns of other cores on the Tagus shelf (Fig. 4.7). Our results from nearby core GeoB-8903-1 (Figs. 4.5 and 4.6) suggest

| Archaeological period | yrs. BC/AD         | cal BP          |
|-----------------------|--------------------|-----------------|
| Middle Ages           | 400-1500 AD        | 1550-450        |
| <i>Islamic period</i> | <i>711-1492 AD</i> | <i>1239-458</i> |
| Roman Era             | 250 BC-400 AD      | 2200-1550       |
| Iron Age              | 650-250 BC         | 2600-2200       |
| Bronze Age            | 1750-650 BC        | 3700-2600       |

**Table 4.3** | Archaeological chronology for the Iberian Peninsula (Schattner, 1998; Figueiral and Carcaillet, 2005).

that increased MS values and decreased grainsize were caused by reduced winnowing due to an increased influx of suspended sediment caused by increased Tagus water and sediment discharge. This is corroborated by Thorndycraft and Benito (2006b) who attribute increased fluvial activity since 1300 cal BP in the Spanish part of the Tagus catchment to increased human impact.

### Anthropogenic impact on sedimentation

The Tagus catchment is large and the data presented in this study are obtained from the downstream end of the catchment. Therefore, the records in the Lower Tagus Valley and on the shelf provide a smoothed, time-integrated signal of deposition. Upstream of the Lower Tagus Valley (Fig. 4.1) the Tagus is situated in an about 300 km long incised V-shaped valley. Therefore, water and suspended sediment is rapidly transported downstream, thus enabling a link between catchment erosion and sediment deposition in the Lower Tagus Valley. In addition, the intense precipitation in the Tagus catchment during winter storms leads to strong erosion on bare soils and high peak floods.

The four depositional phases that have been distinguished above (Fig. 4.7) will be compared with records of human activity in the Tagus catchment. The first human cultivation on the Iberian Peninsula occurred between 6000 and 5000 cal BP (the Neolithic) (Savory, 1968; Múgica *et al.*, 1998; Jorge, 1999).

#### *Depositional phases 1 and 2 | around ~2300 and ~1600 cal BP*

Depositional phase 1 occurred around ~2300 cal BP, which coincides with the late Iron Age-early Roman Era and phase 2 occurred around ~1600 cal BP, which is at the end of the Roman Era (Table 4.3). On land, only the oldest phase was registered in the sediments close to the river, without showing a grainsize change (0501.016 and .025; Figs. 4.3 and 4.4). On the shelf, the mudbelt cores registered both phases (Fig. 4.7, Nos. 1 and 2) and in GeoB-8903-1 this coincides with a temporally finer grainsize. On the shelf sediments deposited before ~2300 cal BP were coarse due to relatively strong winnowing.

An increased influx of fine-grained sediment caused subdued winnowing and accumulation of fine-grained sediment.

The modest grainsize changes, sedimentation-rate changes and small MS peaks, imply that sediment supply remained relatively stable during these phases and the increase of Tagus runoff and flooding were probably limited. In the lower Muge valley (Fig. 4.1), a tributary of the Lower Tagus River, increased sedimentation was registered since ~2150 cal BP, which has been attributed to human impact on catchment vegetation (Van der Schriek *et al.*, 2007a).

In the Tagus catchment small-scale vegetation changes were registered between ~2300 and ~1600 cal BP. Around 2500 cal BP a period of local deforestation and over-grazing was registered in the Portuguese Serra da Estrêla (Van den Brink and Janssen, 1985; Van der Knaap and Van Leeuwen, 1995). During the Iron Age, landscapes became more open in central Spain, settlement patterns changed and forest cover progressively degraded, indicating increasing human impact (Atienza *et al.*, 1990; Atienza *et al.*, 1991; Gil-Romera *et al.*, 2008). From ~2000 cal BP onwards vegetation reconstructions indicate that the extent of montane forest in the central Spanish Tagus catchment decreased gradually and signs of human disturbance were detected (Andrade *et al.*, 1990; Andrade *et al.*, 1996; Franco *et al.*, 1997; Múgica *et al.*, 1998). Archaeological evidence suggests that agricultural practices virtually did not change from Roman through Islamic times (711 AD/1239 cal BP), which may be a reason for the limited changes in the sedimentary record until depositional phase 3 (Gerli, 2003).

#### *Depositional phases 3 and 4 | around ~1100 and ~670 cal BP*

From ~1100 cal BP onwards, deposition in the Tagus system changed drastically. On land, grainsize and sedimentation rate of the overbank deposits increased together with strongly increasing MS values (Fig. 4.7, No. 3). At the distal swamp site of core 0501.029 (Fig. 4.2), peat growth abruptly ended to be followed by clay deposition. At that site, the regional pollen composition reveals an increased human impact and sedimentation rate (Fig. 4.2). Around 1100 cal BP, the mudbelt cores registered increased MS values (Fig. 7, No. 3) and simultaneously, marine core GeoB-8903-1 registered a fining grainsize due to an increased suspended sediment flux (Figs. 4.5 and 4.6). The depositional changes reflect an increased supply of sediment and magnetic particles from the Tagus catchment.

The change in deposition reached its maximum around ~670 cal BP (depositional phase 4). The terrestrial sediments show upward coarsening trends, high sedimentation rates and high MS values (Figs. 4.2-4.4). Pollen types associated with human activity and agriculture reach maximum values

**Figure 4.8** | Three maps from the downstream part of the Lower Tagus Valley showing rapid silting of ~30 km of the valley between 1561 and 1800 AD. Maps (A) and (B) are based on maps in Freire (1985) and map (C) is based on two maps (Secretaria d'Estado, 1784; Anonymous, 1800).

(Fig. 4.2). Furthermore, the Tagus channel belt was considerably reworked during the last ~600 years, implying strong fluvial activity (Chapter 3). In all marine cores, MS signals increased (Fig. 4.7, No 4) while grainsize in core GeoB-8903-1 became finer (Figs. 4.5 and 4.6).

In the Lower Tagus Valley, already in the 1100s AD (850 cal BP) rapid growth of sand islands in the river (*mouchões*) occurred (Azevêdo, 2001), probably as a result of increased sediment supply related to catchment deforestation and erosion. The generally young age of the Tagus channel deposits agrees with an increased flooding frequency and/or intensity which also transported coarser sediment further onto the floodplain during floods (Chapter 3). In the Tagus catchment in central Spain major phases of increased flood magnitude were reconstructed for the periods 1000-800 cal BP and 520-250 cal BP and attributed to human impact (Thorndycraft and Benito, 2006a). Furthermore, most radiocarbon dates in their study are from the last ~1300 years, suggesting a large Medieval sediment flux. Historic maps clearly show rapid infilling of the Lower Tagus Valley central basin during the last ~500 years as the result of the increased sediment flux (Fig. 4.8).

Palaeo-environmental and historical data demonstrate the increasing human pressure on the landscape during and after the Middle Ages (1550-450 cal BP). Grazing, burning, agriculture and deforestation increased dramatically, leading to the disappearance of natural vegetation and strong erosion of organic top soils (Van den Brink and Janssen, 1985; Janssen, 1994; Van der Knaap and Van Leeuwen, 1995; Múgica *et al.*, 1998). Since 1273 AD (677 cal BP) millions of sheep destroyed the vegetation along their migration routes, causing slope erosion (Gerli, 2003). It was only at the end of the 1600s AD

(350 cal BP) that landscape degradation was halted with the establishment of new laws (Klein, 1920; Slicher van Bath, 1960). Mining of ores was of minor importance in terms of sediment supply, since large ore occurrences are rare within the Tagus catchment. However, metal production required much wood, which may have originated partly from the Tagus catchment, adding to the deforestation (Smith, 1979). Regeneration of Mediterranean evergreen forest was difficult due to the marked seasonality of the Mediterranean climate, combined with fire and overgrazing. This resulted in development of a secondary forest—garrigue or maquis—which easily degraded to pasture susceptible to erosion (Tomaselli, 1977; Williams, 2000).

The identified increased sediment flux during especially the last ~1100 years, is most comfortably explained by increased sediment supply from the Tagus catchment due to land-use changes within the catchment in general. The increased sediment delivery to the river and the higher discharges probably occurred due to a reduced vegetation cover, evapotranspiration and water holding capacity of the soil as found all over the globe (e.g. Bosch and Hewlett, 1982; Knox, 2000; 2001; 2006; Andréassian, 2004; De Moor *et al.*, 2008).

## 4.5 CONCLUSIONS

During the last 2300 years in the Lower Tagus Valley floodplain, grainsize coarsened, sedimentation rate increased up to threefold, LOI values decreased and magnetic susceptibility increased. Contrary to the floodplain, on the Tagus mudbelt on the shelf grainsize fined, together with an up to three times higher sedimentation rate and increased magnetic susceptibility values. These sedimentary changes in the floodplain can be related to an increased flooding frequency and/or intensity, supplying coarser sediment onto the floodplain. Increased magnetic susceptibility values have been interpreted by increased deposition of eroded soil material from the upstream catchment.

The fining grainsize on the offshore mudbelt is explained by an increased suspended sediment flux towards the shelf. The higher concentration of fine mud resulted in subdued winnowing and therefore a better preservation of fine-grained sediment. Furthermore, the higher concentration of suspended sediment probably led to a larger depositional flux.

The radiocarbon age framework and sedimentary characteristics provide a tool to correlate terrestrial and marine sediments and to distinguish synchronous depositional phases. Depositional phases 1 (around ~2300 cal BP) and 2 (around ~1600 cal BP) show minor changes in grainsize, sedimentation rate and magnetic susceptibility. Depositional phases 3 (around ~1100 cal BP) and 4 (since ~670 cal BP) show large changes in grainsize, sedimentation

rate and magnetic susceptibility. Climate impact on the sedimentary records could not be established and most of the sedimentary changes can be related to increased human impact in the Tagus catchment.

# CHAPTER 5

The present paper aims to reconstruct Tagus flooding history for the last ~6500 years, and to explain fluvial activity changes in terms of allogenic (climate, human impact) and autogenic (system intrinsic) processes. The flooding history has been determined by cored sedimentary records located ~18 km apart in distal, low-energy backswamps on both sides of the Tagus channel. In these low-energy backswamps, fine-grained sediment layers deposited from suspended load of overbank flood water, reflect periods with multiple overbank floods. By means of a multi-proxy approach (sedimentology,

## Holocene flooding history of the Lower Tagus Valley (Portugal)

magnetic susceptibility, grainsize, loss-on-ignition, carbonate content and pollen) sedimentary and environmental changes were identified. At both sites, synchronous lithological intervals accumulated, implying a regional origin for the changes in fluvial activity since ~6500 cal BP. Based on lithological changes, three phases of high fluvial activity (6500-5500, 4900-3500 and 1000-0 cal BP) and two phases of low fluvial activity (5500-4900 and 3500-1000 cal BP) were identified. The progressive decline of regional forest since the end of the African Humid Period (~6000 cal BP) is not reflected in the Tagus flooding history by increased (peak) flood discharges. The dominant allogenic controls of fluvial activity in the Lower Tagus Valley were relative sea level (6500-5500 cal BP), climate (5500-1000 cal BP), and human impact (1000-0 cal BP).

## 5.1 INTRODUCTION

In northern Tunisia, phases of increased fluvial activity alternating with periods of soil formation have been matched with short-term North Atlantic cooling events (Zielhofer and Faust, 2008). In slackwater deposits of the Spanish Llobregat River periods reflecting increased flooding have been identified for the last 2700 years (Thorndycraft *et al.*, 2005). Further, a database of Spanish radiocarbon dated fluvial units has been used to investigate the relationship between environmental changes and Holocene flooding dynamics (Macklin *et al.*, 2006; Thorndycraft and Benito, 2006a, b; Benito *et al.*, 2008). Six clusters of increased fluvial activity since ~11,000 cal BP have been recognised in the middle Spanish reach of the Tagus River using slackwater deposits and palaeo-flood water-level indicators (Benito *et al.*, 2003c). Phases of increased flooding were associated with regional climatic or environmental changes (Benito *et al.*, 2003b). The Tagus sites mentioned above, are located in the middle bedrock-confined reach of the Tagus River with a lack of data between 7000 and 1000 cal BP (Benito *et al.*, 2003c). In addition, in the middle-reach sites the signal from large downstream Portuguese tributaries is missing.

On the Tagus continental shelf, marine records have been studied for palaeo-discharges and climatic changes, especially for the last 2000 years. Abrantes *et al.* (2005) established a correlation between Tagus discharge and climatic variability during the last two millennia. Discharge was low during the Medieval Warm Period (MWP; 1400-650 cal BP) and increased during the Little Ice Age (LIA; 650-50 cal BP). They attributed the lower discharge during the MWP to a more persistent positive North Atlantic Oscillation (NAO) state or more frequent extreme NAO maxima, while the LIA is coupled to a more persistent negative NAO state or more frequent extreme NAO minima, causing more precipitation and discharge (Abrantes *et al.*, 2005; Lebreiro *et al.*, 2006).

The studies cited above show that the Holocene Tagus flooding and discharge history are still fragmentary. The upstream bedrock-confined Tagus reach contains large hiatuses, while offshore marine studies only cover the last ~2000 years of Tagus palaeo-discharges. Records from the aggrading Holocene floodplain in the Lower Tagus Valley (LTV) have not been studied yet in terms of flooding history. The sediments contain a continuous record of overbank deposition and indications for climate change. Flooding history in the Lower Tagus Valley has only been studied for the period 1855-1998 AD (Azevêdo *et al.*, 2004). Therefore, this chapter aims to reconstruct Tagus flooding history for the last ~6500 years, which is the maximum age of Lower Tagus Valley fluvial deposits (Chapter 3) and to explain fluvial activity changes in terms of allogenic (climate, human impact) and autogenic (system intrinsic)

**Figure 5.1 |** Location map of the Lower Tagus Valley: (A) Tagus catchment and location of Lower Tagus Valley on the Iberian Peninsula, Digital Elevation Data from Jarvis *et al.* (2006); (B) the Lower Tagus Valley and location of study area; (C) study area and location of cross sections and corings. Coordinates (X-Y) in European Datum 1950/UTM Zone 29N.

processes.

Two Lower Tagus Valley sites with low-energy backswamp conditions at opposite sides of the river channel were selected, in order to extract the regional fluvial activity signal (Paul do Boquilobo and Vale de Atela, Fig. 5.1). The sediments accumulated during the last ~6500 years and contain alternating fine-grained and organic layers (gyttja, peat and humic clay). To reconstruct floodplain geometry two cross sections from a previous study were used (Chapter 3), one of which was combined with new data (Figs. 5.2 and 5.3). A twofold approach was used for the analyses of cores: a sedimentological approach consisting of the determination of grainsize, magnetic susceptibility (MS), loss-on-ignition (LOI) and carbonate content and an ecological approach consisting of pollen-based vegetation reconstruction.

The Tagus River has a length of ~1000 km and a catchment area of 80,630 km<sup>2</sup> (Bettencourt and Ramos, 2003; Le Pera and Arribas, 2004). The Tagus originates at an elevation of about 1600 m in eastern Spain (Fig. 5.1) and flows westwards to the NNE-SSW oriented Lower Tagus Basin (LTB). The average discharge near its mouth is 400 m<sup>3</sup>/s, but the river is characterised by extreme seasonal and annual discharge variability with peaks more than 30 times the average (Benito *et al.*, 2003a; Bettencourt and Ramos, 2003).

## 5.2 METHODS

The distribution of Lower Tagus Valley facies units and palaeogeography have been described previously (Chapter 3). Based on this large-scale framework, two sites have been selected with the most complete Holocene record. Cross sections at these sites have an average coring spacing of 300 m. Coring locations were measured using a Garmin GPS-12 receiver (horizontal resolution ~5 m) and the elevation relative to mean sea level (m.s.l.) was measured using Trimble DGPS equipment (vertical resolution ~5 mm). Elevations of the coring locations in Vale de Atela were deduced from detailed surface elevation measurements (INETI, 1994). The manual corings were done using Edelman augers for sediment above the groundwater table and the gauge and the Van der Staay suction-corer for sediment below the groundwater table (Van de Meene *et al.*, 1979). The sediments were described in the field following the method explained in Berendsen and Stouthamer (2001) and lithological classifications were converted to USDA terminology. Cores 0501.029 and 0701.016 were taken using a gauge and core ALPIII was taken using a Livingstone sampler.

In low-energy backswamps, fine-grained deposits accumulate when discharge exceeds the bankfull stage. In that situation fine-grained sediment is

deposited from suspended load of overbank flood water. A period with such events is registered in the sedimentary record as a fine-grained sediment layer, reflecting multiple overbank floods. In regions with sufficient rainfall and/or groundwater seepage, a decrease in the number of overbank floods, leads to accumulation of organic layers (Törnqvist and Van Dijk, 1993). A radiocarbon date from the top of such organic layers, underlying fine-grained overbank deposits, gives the age of the onset of river sedimentation. The end of river sedimentation can be dated with a sample from the base of an organic layer overlying the fine-grained deposits (e.g. Törnqvist and Van Dijk, 1993; Berendsen and Stouthamer, 2000). Because accumulation of organic layers occurs first in the low-lying centre of a floodbasin, that area is best suited to register changes in fluvial activity (Van Dijk *et al.*, 1991).

In low-lying areas which aggrade rapidly, like the Lower Tagus Valley, it is generally assumed that important hiatuses are absent at lithological boundaries (Törnqvist and Van Dijk, 1993). However, because organic material from layers either below or above the fine-grained layer is dated, a somewhat older respectively younger age is obtained, which does not directly reflect the onset or end of sedimentation (see also discussion in Van Dijk *et al.*, 1991; Törnqvist and Van Dijk, 1993). When sampling the cores for the present study, no recognisable erosional contacts were observed.

### Sample treatment

Grainsize was measured on cores 0501.029 (207 samples) and 0701.016 (147 samples) at 5-10 cm intervals using a Fritsch A22 Laser Particle Sizer which resulted in grainsize distributions in the range of 0.15-2000  $\mu\text{m}$ . Samples were prepared following the methods described by Konert and Vandenberghe (1997). This implies that sediment with a grainsize smaller than 8  $\mu\text{m}$  corresponds with clay. Grainsize statistics (mean and D90 = grainsize at which 90 % is finer) were calculated using the program GRADISTAT (Blott and Pye, 2001).

Mean clastic sedimentation rates were derived by calculating the mean proportion (%) of clay, silt and sand for each phase. This value was divided by 100 (%) and subsequently multiplied by the total clastic sedimentation rate for each phase. The total clastic sedimentation rate is the mean proportion of clastic material for each phase, divided by 100 (%) and multiplied by the total sedimentation rate (including non-clastic material); thus it is the clastic fraction of the total sedimentation rate.

A LECO TGA-601 was used to determine the LOI of 229 (core 0501.029) and 147 (core 0701.016) dried and grounded samples of approximately 2 g. During the first step of the treatment, samples were heated to a maximum of 105°C. Moisture evaporated from the sample and when the

weight remained constant with a maximum deviation of 0.5 % during 9 minutes, the dry weight of the sample was measured ( $W_{dr}$  (g)). Subsequently, the temperature was raised to 335°C with a rate of 10°C/min. The atmosphere in the oven consisted of 100 % oxygen and all easily combustible organic carbon was burned during this time interval. In order to determine the “classic” LOI, the temperature in the oven was further raised to 550°C with a rate of 10°C/min in a flow of normal air. When the weight remained constant within 0.5 % during 9 minutes, the residue was weighed ( $W_{gl}$  (g)) and  $W_{550}$  (in %) was calculated using:  $W_{550} = ((W_{dr} - W_{gl}) / W_{dr}) \cdot 100$  %.  $W_{550}$  is considered equivalent to the “classic” LOI<sub>550</sub>. Due to the heating, structural water and -OH bounds in the (clay) minerals were lost as well, causing an overestimation of the LOI; mostly this overestimation is equal to 7 % of the clay-content. Core 0701.016 contained no carbonate. The temperature for the 229 samples of core 0501.029 was raised to 1000°C with the same rate as before to determine the carbonate content. The sample was weighed again at 615°C ( $W_{615}$  (g)). To decelerate the dissociation of carbonates, the atmosphere in the oven consisted of a medium flow of pure CO<sub>2</sub>. When the weight remained constant within 0.5 % during 9 minutes at 1000°C, the residue was weighed ( $W_{1000}$  (g)). The weight loss between 615 and 1000 °C is the weight loss of carbonates  $W_{car} = W_{615}$  (g) -  $W_{1000}$  (g). Carbonate content was calculated using:  $(W_{car} / W_{dr}) \cdot (100/44) \cdot 100$  %.

Pollen samples (112) were prepared following the description by Faegri and Iversen (1975); the material was sieved through a 7-8 µm nylon mesh and clastic material was removed using a sodium polytungstate heavy liquid separation. Samples were embedded in glycerine jelly and sealed with paraffin wax and determined at the Friedrich-Schiller University in Jena (core 0501.029) and Utrecht University (core ALPIII). Pollen counts are presented as regional diagrams and diagrams of selected taxa are presented together with local ecological summary diagrams.

The regional diagrams were constructed using tree pollen (*Acer*, *Betula*, *Corylus*, *Fagus*, *Juglans*, *Pinus*, *Quercus*-type, *Tilia*, *Olea europaea*, *Ulmus*-type, *Fraxinus*-type, *Viburnum*-type), shrub pollen (*Cistus*-type, *Erica*-type) and herb pollen (*Polygonum aviculare*, Apiaceae, Asteroideae, Brassicaceae, *Callystegia*-type, Caryophyllaceae, *Centaurea*-type, Cichorioideae, Fabaceae, *Galium*-type, *Hypericum perforatum*-type, *Plantago*-type, Poaceae, Ranunculaceae, *Rhinantus/Parentucellia*-type, *Rumex acetosella/bucephalophorus*-type, *Sanguisorba minor*, *Sanguisorba officinalis*, *Veronica*-type, *Artemisia*, Campanulaceae, *Echium*-type, *Urtica*, *Xanthium*-type, *Cannabis/Humulus*-type, Lamiaceae, Cereal, *Polygonum amphibium*, *Polygonum persicaria*, *Helianthemum*, *Juniperus*-type, *Phillyrea*, *Pistacia*-type, *Ruta chalepensis*, *Tamarix*, *Alisma*, *Asplenium*, cf. *Trollius*). In the local ecological diagrams aquatics (*Iso-*

etes, *Myriophyllum*-type, *Nuphar*, *Nymphaea*), wetland (*Cyperaceae*, *Lythrum*, *Typha*, *Sparganium erectum*-type, *Equisetum*) and carr (*Alnus*, *Salix*) pollen were plotted. For core 0501.029 vegetation indicating groundwater seepage (*Myriophyllum*-type and *Equisetum*) was plotted as well, calculated as percentage of the local pollen sum.

Core ALPIII was collected in 1985 by Van Leeuwaarden and colleagues from Utrecht University in Vale de Atela. The unpublished pollen record and radiocarbon dates were kindly provided by him for use in this study.

Thirteen radiocarbon dates were used to construct the chronological framework (Table 5.1). The radiocarbon samples consisted as much as possible of terrestrial botanical macrofossils (Törnqvist *et al.*, 1992; Törnqvist and Van Dijk, 1993) that were manually selected from generally 1 cm thick sediment slices, otherwise bulk samples were used. Radiocarbon ages were calibrated using the program OxCal v3.10 (Bronk Ramsey, 1995, 2001, 2005) using the atmospheric data from Reimer *et al.* (2004). Radiocarbon ages are expressed as calibrated calendar ages (cal BP) with age spans at the  $2\sigma$  range. Transitions between fluvial activity phases were dated using linear interpolation between dated levels.

Cores were scanned for magnetic susceptibility (MS) using Multi Sensor Core Logging 7.6 (MSCL) equipment (Geotek Ltd.), mounted with a MS2C Bartington magnetic susceptibility meter with loop sensor. Core 0501.029 was measured every 0.5 cm and core 0701.016 every centimetre during 10 s. The upper metres of the cores were recovered using an Edelman auger; in that case, each data point represents the average MS of a ten centimetre interval.

## 5.3 RESULTS

### Tagus floodplain lithostratigraphy

At the base of the Golegã cross section (Fig. 5.2), poorly sorted, mainly coarse-grained sand and gravel were found (Table 5.2), which are interpreted as buried fluvial terrace deposits (FU-1A), probably of Pleistocene age (Chapter 3). The depression in the surface of FU-1A in the northwest of the cross section is interpreted as the incised palaeovalley of Rio Almonda. The basal ~2 m of sediment within this palaeovalley consist of structureless clay and silty clay belonging to brackish water marshes and tidal flats (FU-3A). Deposition of this unit ended shortly after 6860-6630 cal BP (GrA-31004).

In the southeast of the cross section, clay and (silty) clay loam with sand laminae (Table 5.2) are interpreted as deposited by intertidal and subtidal

**Figure 5.3 (previous page)** | Almeirim-Vale de Atela cross section, partly modified after Fig. 3.4: core numbers 0501; and partly based on this study: core numbers 0701. Distribution of facies units is based on manual corings. Note the low elevation of the Vale de Atela valley floor due to limited clastic deposition and compaction. A full-colour version of this cross section can be found in *Addendum 1*.

flats (FU-3B), deposited in the incised early Holocene Tagus valley (Chapter 3). Deposition of these tidal deposits ended shortly after 7270-7020 cal BP (GrA-32655). The overlying Tagus channel sediments consist of gravel-rich, medium to coarse-grained sand in a fining-upward sequence (FU-8).

The terrace deposits (FU-1A) in the central part of the cross section are overlain by clay-dominated condensed floodbasin deposits (FU-6A) with traces of soil formation and local peaty intervals (Table 5.2). Sedimentation rate was low, as testified by the pedogenesis in these relatively consolidated floodbasin deposits and deposition started 6680-6480 cal BP (GrA-30615). On top of this unit, silt and clay-dominated floodbasin deposits were found, containing some palaeosols (FU-6B), of which the upper one was dated at ~850 cal BP (Chapter 3). This unit forms a southward thinning wedge of floodbasin deposits in the Lower Tagus Valley (Chapter 3). Deposition of FU-6B started around 3390-3210 cal BP (UtC-14747) and simultaneously natural levees (FU-7) were deposited, consisting of laminated loam, silt loam and well-sorted, fine sand.

The low elevation (lowest point at ~12 m m.s.l.) of the Paul do Boquilobo backswamp surface (Fig. 5.1) results from the buried palaeovalley of Rio Almonda and the large distance from the Tagus channel (Fig. 5.2), implying that only during floods sediment was supplied to this site. Some local, coarser-grained deposits originate from the local stream Rio Almonda. During the Holocene, the Tagus channel was always located ~4 km from this site. Therefore low-energy conditions prevailed and a complete Holocene record accumulated slowly, in which alternating fine-grained and organic layers reflect fluvial activity, rather than lateral Tagus channel migration.

At the base of the Almeirim-Vale de Atela cross section (Fig. 5.3), poorly sorted, coarse-grained gravely sand was found (FU-1B, Table 5.2). In the Tagus valley, this unit has a steep downstream gradient (~60 cm/km) and is interpreted as a braided river deposit resulting from Late Pleistocene relative sea-level lowstand (Chapter 3). These deposits do not seem to have a steep gradient in the downstream part of Vale de Atela because the cross section does not exactly follow the valley axis (Fig. 5.3). The basal unit was deposited before 9030-8750 cal BP (GrA-32584).

The basal unit is overlain by structureless soft clay and silty clay deposited in brackish water marshes and tidal flats (FU-3A, Table 5.2). This unit was deposited between 9030-8750 cal BP (GrA-32584) and 7010-6740 cal BP

| Facies Unit | Interpretation                         | Lithology   | Details   |
|-------------|--|---|---|
| 1A          | fluvial terrace deposits               | very fine to coarse-grained sand, usually poorly sorted and with gravel   | compact sediment, unit has flat top and slopes seaward, incised into Miocene-Pliocene deposits  |
| 1B          | high-gradient fluvial channels         | fine to coarse-grained, angular sand, poorly sorted, with increasing gravel to base   | plant roots in top<br>fining-upwards, unit has rather flat top morphology and slopes seaward, incised into Miocene-Pliocene deposits  |
| 3A          | backwash water marshes and tidal flats | generally structureless clay and silty clay with locally very fine sand lamination.   | pyrite crystals and pyrite in diatoms, foraminifera and plant remains, bioturbation. Top 1.5-2 m + m.s.l.: very firm consistency, angular blocky structure, carbonized plant material, many carbonate concretions = pedogenesis<br>Underneath: soft, shell-like breaking, no ripening   |
| 3B          | intertidal and subtidal flats          | plastic, soft clay and (silty) clay loam with laminae and lenses of very fine to coarse-grained sand with some gravel.<br>Clay-sand contacts sharp  | Some sand layers disturbed and preserved as sand nests or spots = bioturbation  |
| 6A          | condensed fluvial floodbasins          | sandy loam, loam, silt loam and (silty) clay loam and humic clay, peaty clay and peat intervals   | located on top of FU-1, rough consistency, small carbonate concretions, root traces, white & green spots, animal bioturbation, admixture of sand grains. Locally greenish, bluish colours. Alternating wet and dry conditions   |
| 6B          | fluvial floodbasins                    | silt loam, (silty) clay loam and clay, very locally poorly sorted (loamy) coarse-grained sand with gravel deposited by small brook channels. Distal areas: gyttja, peat, peaty clay and humic clay layers | unit forms southwards thinning wedge. Ongoing sedimentation on active floodplain with shallow (ephemeral) flood-channels at surface. Contains iron-oxides, iron-concretions, manganese spots, carbonate concretions and is well oxygenated. More charcoal to top. A-horizons: ≤ 50 cm, dark brown-grey to dark brown, sometimes hard, dry and crumbly with white lines (no carbonate) |
| 7           | natural levees and crevasses           | sandy loam, loam, silt loam and usually well sorted very fine to fine-grained sand in laminae   | present on both sides along Tagus channel (FU-8). Shallow (ephemeral) flood-channels at surface. Often much charcoal present. Locally medium to coarse-grained sands, some in channels or displays  |
| 8           | fluvial channels                       | medium to coarse-grained sand, with some gravel channel lags.   | fining-upwards, pebbles & cobbles dominated by quartz & quartzite (≥ 93%), up to 5% granite, sand has colourful, "clean" appearance, charcoal present. In coring GOL: several stacked fining-upwards sequences  |

**Table 5.2 |** Summary of facies unit (FU) characteristics in the Golegã and Almeirim-Vale de Atela cross sections.

(UtC-1983). In the Tagus valley, pedogenesis and soil ripening took place in the marsh deposits, which accumulated ~2 m above m.s.l., equivalent with the spring tidal level (Portela and Neves, 1994; Bettencourt and Ramos, 2003). In Vale de Atela however, the top of this unit is found around ~0 m m.s.l. and no pedogenesis has taken place (Fig. 5.3).

In the Tagus valley FU-3A is overlain by silt, clay and organic deposits of fluvial floodbasin origin (FU-6B). In the tributary Vale de Atela, FU-6B consists of organic-rich freshwater deposits (Table 5.2), which possibly resulted from local groundwater-table rise due to damming of the tributary valley entrance by more rapid aggradation in the main Tagus valley (Fig. 5.3). The wet situation in Vale de Atela persisted by continuous Tagus valley aggradation, causing a continuous rise of the groundwater table and accumulation of organic deposits. In Vale de Atela, FU-6B can be subdivided into two subunits. The basal subunit, deposited since 7010-6740 cal BP (UtC-1983), is peat-dominated (Fig. 5.3) with remains of *Alnus* and *Salix* wood and reed. The upper subunit, deposited since ~1000 cal BP as supported by charcoal, brick and pottery fragments, is silt and clay-dominated, with little organic material. Coeval with FU-6B, natural levee deposits consisting of laminated loam, silt loam and well-sorted fine sand (FU-7) accumulated. The Tagus and Vale de Atela channels (Fig. 5.3) consist of medium to coarse-grained sand in fining-upward sequences (FU-8).

The low elevation of the present-day Vale de Atela valley floor is the result of limited clastic sediment deposition and compaction of the organic valley-fill deposits. This is supported by the mean clastic sedimentation rate (~0.9 mm/y, Fig. 5.5i), which is about half that of the Tagus valley (core 0501.016, Chapter 4). Although the local stream Vale de Atela also supplied sediment, its small catchment (~80 km<sup>2</sup>) and limited representation in the sedimentary record, suggest relatively minor importance compared to the Tagus River. Furthermore, core data clearly show fine-grained sediment layers originating from the Tagus valley (FU-6B, Fig. 5.3). During the last ~6500 years, backswamp conditions persisted in the sheltered tributary valley behind the Tagus levees and especially Tagus floods supplied suspended sediment, enabling the reconstruction of the Tagus flooding history.

### Core sedimentology

Core 0501.029 is dominated by clay layers and clay content is generally above 50 % (Fig. 5.4a, b). Core 0701.016 is dominated by peat layers (Fig. 5.5a, b), implying very low-energy backswamp conditions. Furthermore, mean clastic sedimentation rate is lower in core 0701.016 (~0.9 mm/y, Fig. 5.5i) than in core 0501.029 (~1.2 mm/y, Fig. 5.4j). However, the grainsize of core 0701.016 is generally coarser than that of core 0501.029. Especially the most organic in-

**Figure 5.4** | Core 0501.029 from Paul do Boquilobo (location, see Fig. 5.1): a) lithology (C = clay, P = peat, S = sand); b) grainsize distribution; c) magnetic susceptibility; d) mean grainsize; e) D90 grainsize; f) fine sand fraction; g) coarse sand fraction; h) loss-on-ignition (LOI); i) carbonate content; j) mean clastic sedimentation rate (see Methods); k) reconstructed flooding phases (see text for explanation). Note that the lowest clay interval is of tidal origin.

**Figure 5.5** | Core 0701.016 from Vale de Atela (location, see Fig. 5.1): a) lithology (C = clay, P = peat, S = sand); b) grainsize distribution; c) magnetic susceptibility; d) mean grainsize; e) D90 grainsize; f) fine sand fraction; g) coarse sand fraction; h) loss-on-ignition (LOI); i) mean clastic sedimentation rate (see Methods); j) reconstructed flooding phases (see text for explanation). Note that the lowest clay interval is of tidal origin.

tervals show low clay content and relatively high silt and sand contents. When considering that fine-grained sediment is deposited from suspended load of overbank flood water, the relatively high content of fine and coarse-grained sand in the organic intervals implies that the sediment in the cores probably originated from different sources. Besides deposition by Tagus floods, local sources have also delivered sediment to the sites. Both sites are located far away from the Tagus channel and close to the sandy deposits along the valley sides. In such a situation it is likely that local, relatively coarse-grained sediment sources (local streams, colluvium, aeolian) dominate over regional, fine-grained sediment sources (Tagus) during periods of low fluvial activity (peat formation). Therefore, the grainsize patterns can not be used as a one-to-one proxy for Tagus fluvial activity as it is derived from different sources.

### *Basal interval*

The basal coarse sand interval (12.5–12 m depth) in core 0501.029 (Fig. 5.4a) is part of the fluvial terrace deposits of FU-1A. The overlying soft, silty clay interval (12–10.4 m) with high MS values (Fig. 5.4c) was deposited by a brackish water marsh (FU-3A) until 6860–6630 cal BP (GrA-31004). At the base of core 0701.016 (Fig. 5.5a) a similar soft, silty clay interval (8–7 m) with high MS was found (Fig. 5.5c), which was deposited by a brackish water marsh until 7010–6740 cal BP (UtC-1983), when tidal conditions abruptly ended due to cessation of relative sea-level rise (Chapter 3). The high MS values in these intervals result from pyrite (visually identified using a microscope) and associated iron sulphide minerals (Kattenberg and Aalbersberg, 2004).

### *Phase 1*

In core 0501.029, the tidal deposits are overlain by a (humic) clay-dominated interval (10.4–8.8 m) with low MS, LOI and carbonate values (Fig. 5.4c, h, i). Deposition started around 6680–6480 cal BP (GrA-30615) and ended ~5580 cal BP (Fig. 5.4a). In core 0701.016, the tidal interval is overlain by a thin interval (6.9–6.6 m) with (humic) clay layers and an organic soil horizon. In both cores this interval with generally low LOI and carbonate content (Figs. 5.4h, i and 5.5h), is interpreted to represent a phase with relatively high fluvial activity (i.e. increased overbank sedimentation due to increased (peak) flood discharge), prohibiting peat accumulation. This is corroborated by relatively high mean clastic sedimentation rates (Figs. 5.4j and 5.5i). Generally, this oldest fluvial phase occurred between ~6500 and 5500 cal BP (Figs. 5.4 and 5.5, Phase 1). This interval is thicker in core 0501.029 than in core 0701.016, because fluvial aggradation and deposition started earlier in the north (Chapter 3).

### *Phase 2*

The interval between 8.8–8.1 m in core 0501.029 is peat-dominated, with LOI values up to 78 % (Fig. 5.4h). The clastic fraction in the peat is clay-dominated (Fig. 5.4b). A peak of coarse sand (~15 %, Fig. 5.4g) within the interval with the highest LOI values (~78 %, Fig. 5.4g), is interpreted to reflect a local sediment source. Accumulation of this interval ended ~5,040 cal BP. Core 0701.016 contains a similar peat interval (6.6–5.9 m) with LOI values up to 56 % (Fig. 5.5h). Silt and sand dominate the clastic fraction (Fig. 5.5b) and some coarse sand is present (Fig. 5.5g). A coarse sand peak (~10 %, Fig. 5.5g) coinciding with a high LOI value (~51 %, Fig. 5.5h), is interpreted as an organic layer which accumulated during low fluvial overbank sedimentation, leading to a relatively increased importance of coarse-grained local sediment sources. The coarsening-upward grain size in this peat interval possibly reflects build-up of the fluvial wedge in the main Tagus valley. Peat accumulation ended ~4815 cal BP. At both sites the peat accumulated between ~5500 and 4900 cal BP (Figs. 5.4 and 5.5, Phase 2). The synchronicity indicates that this phase was characterised by relatively low Tagus fluvial activity, resulting in undisturbed peat growth. Low fluvial activity results in less sediment supply, as supported by lower mean clastic sedimentation rates (Figs. 5.4j and 5.5i).

### *Phase 3*

In the humic, silty clay interval in core 0501.029 (8.1–6 m), the relatively large grain size fluctuations (Fig. 5.4b, e) are possibly due to silt and fine sand fluxes caused by individual Tagus floods. Around 3390–3210 cal BP (UtC-14747) sedimentation of this interval ended. Core 0701.016 contains a similar interval with humic, silty clay-dominated layers separated by thin peat layers (5.9–4.7 m). A coarse sand peak (~18 %, Fig. 5.5g) coincides with a high LOI value (~72 %, Fig. 5.5h) is interpreted as coming from a local sediment source. Deposition of this interval ended ~3660 cal BP. The low LOI content in these intervals (Figs. 5.4h and 5.5h, Phase 3), and the presence of only a few peat layers, implies accumulation during a phase with relatively high fluvial activity with relatively high mean clastic sedimentation rates (Figs. 5.4j and 5.5i), as in Phase 1. At both sites, this interval was deposited between ~4900 and 3500 cal BP.

### *Phase 4(a/b)*

The calcareous gyttja-dominated interval (6–4.7 m) in core 0501.029 contains carbonate values reaching up to 64 % (Fig. 5.4i). The silt content in this calcareous gyttja interval is relatively high (Fig. 5.4b), and some fine and coarse sand peaks occur (Fig. 5.4f, g), suggesting a larger contribution of local sediment sources. The presence of calcareous gyttja implies lacustrine circumstances at

the site. Based on the *Nuphar lutea*, *Nymphaea alba* and *Myriophyllum pectinatum* pollen, water depth probably fluctuated seasonally between 0.5 and 3 m (Hannon and Gaillard, 1997). Carbonate content slowly decreases upwards, probably due to shallowing and peat growth. Calcareous gyttja accumulation ended ~2228 cal BP and was followed by peat accumulation (4.7–3.4 m) with LOI values up to 54 % (Fig. 5.4h). The clastic fraction in the peat is clay-dominated (Fig. 5.4b, j) and some intervals with high LOI values contain peaks of fine and coarse sand (Fig. 5.4f, g), which reflect local sediment sources. Peat accumulated until ~1000 cal BP (UtC-14749 & UtC-14750) when peat growth abruptly ended.

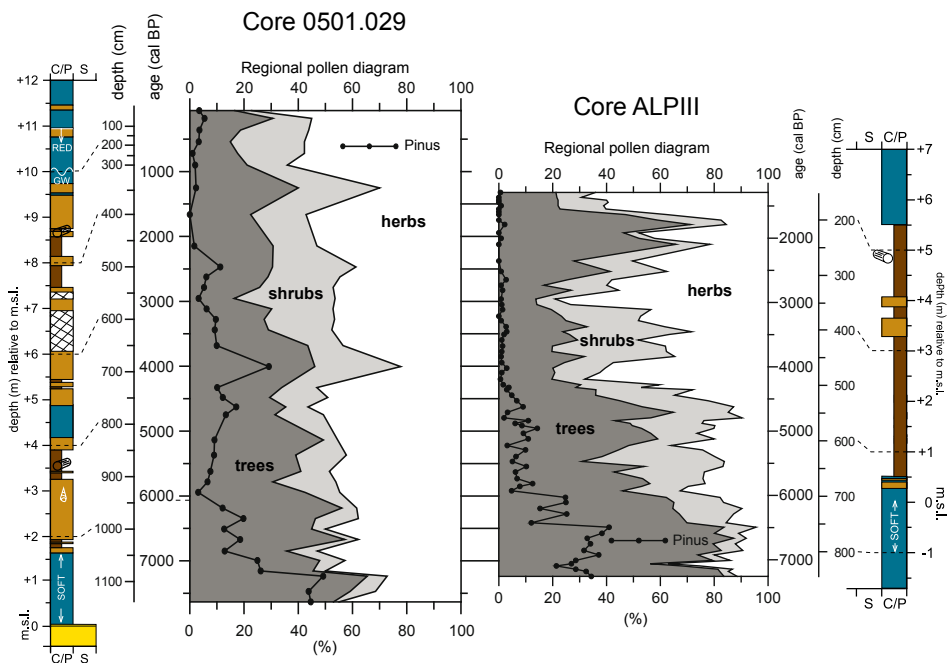

In core 0701.016 (4.7–1.8 m), the equivalent of the calcareous gyttja and peat interval is formed by a peat-dominated interval with LOI values up to 67 % (Fig. 5.5h). The clastic fraction (Fig. 5.5b) is silt and sand-dominated and the mean and D90 grain size (Fig. 5.5d, e) fluctuate, probably reflecting Tagus floods and sediment input from local sources (e.g. Vale de Atela). At ~3.4 m depth, LOI values clearly decrease as a result of clastic sedimentation due to a large flood. Accumulation ended around ~1000 cal BP. The interval with wetter circumstances (Fig. 5.4, Phase 4a) and the overlying peat-dominated interval (Phase 4b) in core 0501.029 and the peat-dominated interval in core 0701.016 (Fig. 5.5, Phase 4) reflect a period with generally low Tagus fluvial activity. This is supported by low mean clastic accumulation rates (Figs. 5.4j and 5.5i). Phase 4 with very wet local conditions occurred between ~3500 and 1000 cal BP.

### Phase 5

In both cores the upper interval is clay and silt-dominated (3.4–0 m, Fig. 5.4; 1.8–0 m, Fig. 5.5) with a coarsening-upward tendency (Figs. 5.4b and 5.5b), strongly increased MS values (Figs. 5.4c and 5.5c) and decreasing LOI values (Figs. 5.4h and 5.5h). The changes in this interval (Phase 5) resulted from increased fluvial activity and increased supply of coarser sediment, which reflect strong human impact in the Tagus catchment (Chapter 4). The increased fluvial activity is corroborated by unprecedented tripling of the mean clastic sedimentation rates (Figs. 5.4j and 5.5i).

### Palynology

The regional pollen diagrams show a general decrease of tree pollen and an increase of shrub and herb pollen (Fig. 5.6). Nine Local Pollen Assemblage Zones (LPAZ) were identified in core 0501.029 (Fig. 5.7) and core ALPIII (Fig. 5.8), based on local vegetation development. The environmental interpretation for each LPAZ mainly reflects local hydrology in terms of permanently wet (groundwater level at or above the ground surface), regularly inundated

**Figure 5.6** | Comparison of regional pollen diagrams for cores 0501.029 (Paul do Boquilobo) and ALPIII (Vale de Atela).

(wet conditions alternated with dry conditions; annually fluctuating local groundwater level), and dry (groundwater level below the ground surface). Human impact can be unrelated to any of these conditions, but it is likely that dryer environmental conditions are preferred for anthropogenic use of these low lying areas.

### Paul do Boquilobo (core 0501.029, Fig. 5.7)

LPAZ PdB-1 (7600-7200 cal BP) | clay

This pollen zone is characterised by relatively high values of *Spiniferites*-type dinoflagellates and *Pinus* pollen. *Pinus* pollen are known to be overrepresented in fine-grained marine sediments, making their high values indicative for a marine environment, while Chenopodiaceae and Cichorioidae pollen are indicative for the presence of salt marsh vegetation. The high values of *Isoetes* in this zone (aquatics curve) are the result of freshwater influence. During high discharge the river flushes the high water channels and carries *Isoetes* spores downstream. Sediments and *Isoetes* spores settle where the river meets the brackish environment, causing a freshwater imprint in a brackish environment. Towards the top of this zone freshwater indicators gradually take over.

Paul do Boquilobo  
Lower Tagus Valley  
Portugal

Analyses: H. Schneider

**LPAZ PdB-2 (7200-6100 cal BP) | humic clay with some peat layers**

Indicators for marine influence (*Spiniferites*-type and *Pinus*) rapidly decline and fresh water aquatic taxa (*Nymphaeae*, *Nuphar*, *Myriophyllum*, *Potamogeton*) appear in the record. Simultaneously, wetland communities (Cyperaceae, *Sparganium*, *Lythrum*, *Mentha*) and reed marsh taxa (Poaceae, and ferns like *Thelypteris* and *Dryopteris*) expand. This hydrosere succession leads to a hampering of the drainage and local wet conditions. In the absence of periodical flooding, seepage indicators (*Equisetum*, *Myriophyllum*) become more prominent in the record. Following this phase, floodplain forest (*Alnus* and *Salix*) increases, which indicates periodical flooding of the site and a progressive growing in with vegetation. This culminates in a completely *Alnus* dominated floodplain forest intermingled with *Vitis*.

**LPAZ PdB-3 (6100-5200 cal BP) | humic clay with peat layer**

The *Alnus*-dominated phase is succeeded by a more *Salix* dominated phase with *Dryopteris*. At the same depth, aquatic taxa (*Isoetes*, *Nuphar*, *Myriophyllum*, *Potamogeton*) are more prominent in the pollen assemblage. This change is indicative for an increase in water depth at the site and more permanently wet conditions the whole year through. Apparently, periodic inundation resulting in *Alnus* floodplain forest, declined. Hence the influence of groundwater seepage takes over (Fig. 5.7).

**LPAZ PdB-4 (5200-4700 cal BP) | humic clay**

In this zone floodplain forest species (*Alnus* and *Salix*) occur in low frequencies and aquatics show minimum values. Instead, Poaceae, *Typha latifolia*, Cyperaceae and *Dryopteris* become more frequent. This indicates a gradual hydrosere succession from *Salix* shrubs and open water towards wetland vegetation, dominated by reed marsh communities.

**LPAZ PdB-5 (4700-4200 cal BP) | humic clay**

The reed marsh changes its composition and becomes dominated by Asteraceae (Asteroideae and Cichorioideae), Brassicaceae and *Centaurea*. Groundwater seepage indicators in this interval are extremely low. The pollen assemblage might indicate an invasion of the reed marsh by ruderal perennials at the expense of the reed marsh taxa. At the same level spores of the liverwort *Phaeoceros* become frequent. This possibly indicates a dying back of the reed marsh due to drought. Later, this dry phase comes to an end, and floodplain forest

**Figure 5.7** | Pollen percentage diagram of selected taxa from Paul do Boquilobo (core 0501.029) with Local Pollen Assemblage Zones (LPAZ). The Grouped Local Pollen diagram contains the pollen types which are indicated ***bold italic***. Pollen counted by H. Schneider. See Fig. 5.4 for a legend of core lithology.

(*Alnus* and *Salix*) starts to increase again.

**LPAZ PdB-6 (4200-3500 cal BP) | humic clay with some peat layers**

At the base of this zone *Alnus*, *Dryopteris* and *Sparganium* return to the pollen assemblage, interpreted as a return to regular flooding. In the ecological diagram (Fig. 5.7) this is reflected by declining wetland vegetation, followed by the spread of floodplain forest (*Alnus* and *Salix*).

**LPAZ PdB-7 (3500-2300 cal BP) | humic clay, calcareous gyttja**

The sudden decline of floodplain forest coincides with the sudden spread of aquatics in the ecological diagram. Furthermore, Poaceae and Cyperaceae increase in the pollen record. It appears that the floodplain forest drowns and is replaced by open water with *Ranunculus aquatilis*, *Nymphaea*, *Nuphar* and *Myriophyllum* species. Bordering on open water, reed marsh communities are present and in some instances *Salix* shrubs. Groundwater seepage indicators are continuously present, suggesting a fairly stable environment. Regular indicators for human impact (*Plantago*, *Rumex acetosella*-type, *Artemisia*, *Urtica*, Brassicaceae, Asteraceae and Cerealia-type) point to anthropogenic use of the uplands in the surrounding area.

**LPAZ PdB-8 (2300-1000 cal BP) | peat with humic clay layers**

The base of this zone represents a very gradual transition whereby aquatics are gradually replaced by reed marsh communities mainly represented by Poaceae, Cyperaceae with some Apiaceae and *Sparganium*. On the dry parts of the floodplain and surrounding area, indicators for animal husbandry (grassland and ruderal communities), arable land and *Olea* cultivation are prominent, reflecting the Roman era. *Salix* is relatively abundant, indicating a permanently wet local environment. The interval where carr suddenly increases possibly reflects decreasing human impact at the end of the Roman era and the following Peoples Migration Period (Visigoths). At this level, river inundations increase and lithology changes from peat to humic clay.

**LPAZ PdB-9 (1000-0) | humic clay changing upwards to clay with some humic clay layers**

Interpretations for the upper part of the diagram are less robust since anthropogenic influence in the pollen record is clearly present. The regional tree values show a strong decline due to deforestation (Figs. 5.6 and 5.7). Pastures and arable land (*Cerealia* pollen) are present in the uplands bordering the Tagus valley and in the drier parts of the floodplain, according to the high values in different grassland communities (Fig. 5.7). The *Olea* curve indicates the presence of olive groves. Locally the *Alnus* forest of the preceding zone (PdB-8)

was replaced by a *Salix* peak, followed by increasing aquatics. Drowning of the vegetation in combination with increasing anthropogenic indicators probably indicates that the clearances promoted the registered increase in fluvial activity.

### **Vale de Alpiarça (core ALPIII, Fig. 5.8)**

#### *LPAZ Alp-1 (7300-6460 cal BP) | clay*

Similar to the Paul do Boquilobo site, this sequence starts with relatively high values for *Pinus*, Chenopodiaceae and Asteraceae liguliflorae which are indicative for a marine or tidally influenced environment; possibly mud flats bordered by tidal marshes. Towards the top of this zone (since ~7000 cal BP) Poaceae starts to increase followed by a Cyperaceae increase. This environmental change may indicate silting up of the environment. Simultaneously, *Isoetes* spores gradually decline probably reflecting decreasing open water brackish environments where *Isoetes* spores concentrate. However, tidal influence remains as indicated by continuously high *Pinus* and Chenopodiaceae values. Possibly brackish and freshwater marshes start to spread in the valley whereby Chenopodiaceae pollen are produced by *Atriplex* species thriving on litter layers trapped in reed marshes. Consequently the aquatics decline, underlining the progressive spread of marshes at the expense of open water.

#### *LPAZ Alp-2 (6460-5600 cal BP) | clay and humic clay with some peat layers*

The *Pinus* pollen decline abruptly and simultaneously *Alnus* pollen increase suddenly. The reed dominated marshes from the preceding zone are replaced by *Alnus* floodplain forest. Since *Alnus* thrives under freshwater conditions and regular fluvial inundations, the registered change must be interpreted in terms of increased fluvial influence at the expense of tidal influence. At the same depth the heather species (*Calluna*, *Erica scoparia*) spread on the uplands bordering the valley, indicating gradual maquis establishment (Fig. 5.8). This may be an effect of dryer regional climatic conditions. Later, wetland vegetation dominated by Cyperaceae becomes more prominent in the local ecological diagram (Fig. 5.8), which can be explained by increased wet conditions in the valley. A risen water table is supported by increased *Salix* and *Isoetes* values towards the end of this zone.

#### *LPAZ Alp-3 (5600-5250 cal BP) | peat*

At the base of this zone, maquis suddenly shows peak values, which is a sign for drought or human impact on the uplands. *Alnus* forest is prominent and the sedge marsh becomes invaded by Poaceae and *Dryopteris*. The drought and concomitant changes in inundation frequency cause an even further sedge and fern decline. As a result, the lower water table in the valley causes the sedge vegetation to die back and short lasting ruderal vegetation with Asteraceae and

Chenopodiaceae to thrive.

#### *LPAZ Alp-4 (5250-4470 cal BP) | peat*

In this phase *Alnus* starts dominating the floodplain forest with *Vitis* as a major constituent. The local ruderal vegetation is replaced by a denser reed marsh in which sedges are important. This change is most likely caused by more seasonal peaked flood discharge. The low maquis in the uplands is partly replaced by oak shrubs of the high maquis. Hence the regional tree values increase (Fig. 5.6). The *Alnus* floodplain forest phase is interrupted around 4900 cal BP by a short phase with increased wetland vegetation, mainly sedges and willow. This phase coincides with a temporal decline in oak forest and an increase in high maquis (Ericaceae). The presence of *Plantago lanceolata* argues for the fact that these vegetation changes could be the effect of slash and burn phases. After this interruption, regional tree values increase again and the oak forest restores. Locally floodplain forest (carr) recovers. Around 4,600 cal BP, regional tree values (*Pinus* and *Quercus*) decline.

#### *LPAZ Alp-5a (4470-3890 cal BP) | peat*

Around 4450 cal BP *Alnus* floodplain forest declines and is replaced by wetland vegetation dominated by Poaceae, *Plantago lanceolata*, *Rumex acetosa/acetosella*, Brassicaceae and Asteraceae. The combination of taxa makes an interpretation as pastureland likely and argues for a human destruction of the floodplain forest in order to create pastureland. The disappearance of *Alnus* floodplain forest allows for the increased penetration of light to the valley floor, favouring *Isoetes* growth on periodically inundated places and *Dryopteris* in the pastureland. The presence of *Cerealia* indicates the presence of arable land on the uplands bordering the valley. Due to reduction of *Alnus* floodplain forest, the fringe zone of the valley, where the valley sides meet the valley floor, is better registered. This zone is pre-eminently the place where upland seepage water surfaces and where *Myrica* shrubs thrive. This phase of human impact ends with a short restoration of *Alnus* forest.

#### *LPAZ Alp-5b (3890-3725 cal BP) | peat*

Human impact on valley floor vegetation temporary declines and the *Alnus* floodplain forest recovers massively. The alder woodland was no longer coppiced and the valley floor was less intensively used as pastureland. Coppiced

---

**Figure 5.8 |** Pollen percentage diagram of selected taxa from Vale de Atela (core AL-PIII) with Local Pollen Assemblage Zones (LPAZ). Note that lithology and depth are from core ALPIII and therefore not equal to core 0701.016. The Grouped Local Pollen diagram contains the pollen types which are indicated ***bold italic***. Pollen counted by W. van Leeuwen. See Fig. 5.5 for a legend of core lithology.

woodland can quickly produce prolific re-growth from the cut stump. In case this re-growth is not cut back or harvested, an *Alnus* floodplain forest quickly establishes.

*LPAZ Alp-6 (3725-3075 cal BP) | peat with some humic clay layers*

The *Alnus* floodplain forest rapidly disappears again and is replaced by sedge-dominated wetland or pastureland. The open vegetation allows for a better registration of the *Myrica* fringe zone of the valley. The peak values of Asteraceae *Bidens*-type refer to local occurrences of *Bidens* spp. on the valley floor, possibly close to the river on periodically exposed nutrient-rich sites. On the uplands, maquis vegetation spreads followed by an increase in oak forest (*Quercus suber*). Like in the preceding zone (ALP-5) the coppicing of *Alnus* forest apparently favoured *Frangula*, since the wood of this species was not of interest to prehistoric man.

*LPAZ Alp-7 (3075-2450 cal BP) | peat with some humic clay layers*

The *Alnus* floodplain forest including *Vitis*, re-establishes while wetland vegetation, mainly sedges, declines. Declining human impact on the vegetation probably allows for this restoration. At the same depth *Isoetes* increases and *Ranunculus*-type and *Potamogeton* reappear in the pollen record. This argues for a return to wet conditions on the valley floor, which is corroborated by a return of *Salix*, reflecting more permanently wet conditions. On the uplands the maquis vegetation declines together with the oak forest.

*LPAZ Alp-8 (2450-1750 cal BP) | peat*

Although locally on the valley floor almost permanently wet conditions prevail, as indicated by peak values of *Salix* in this zone, human impact seems to increase on the uplands, as documented by higher *Cerealia*-type, *Artemisia*, Chenopodiaceae, *Plantago* spec. and *Cistus*-type values (Fig. 5.8). The increase of *Olea* values argues for the establishment of olive grooves. *Myrica* appears to be replaced by *Sambucus* which could have been the result of eutrophication due to human pressure on the landscape.

*LPAZ Alp-9 (1750-1300 cal BP) | peat*

Floodplain forest (*Alnus* and *Salix*) is strongly reduced and replaced by herbaceous vegetation with Poaceae and Cyperaceae. The values of different tree species decrease rapidly and the *Cerealia* curve increases simultaneously with many herbs which are related to pasture and arable land.

Local ecological pollen diagrams reflect local, site-specific factors causing differences in vegetation in the two sites. In an effort to find coeval local

**Figure 5.9 |** Summary diagram of Local Pollen Assemblage Zones (LPAZ) from Paul do Boquilobo (core 0501.029) and Vale de Atela (core ALPIII) pollen diagrams. The third column provides a synthesis of vegetation development based on LPAZ's; intervals represent periods with largely similar local environmental circumstances. Right column (Flooding phase) shows summarised phases of fluvial activity from Fig. 5.10. Note the period of occupation of "Alto do Castelo" near the Vale de Atela site (see text and Fig. 5.1).

floodplain vegetation and environmental changes, a synthesis was developed (Fig. 5.9). Human impact is relatively prominent in Vale de Atela, because core ALPIII is located at ~2 km south east of the Late Copper Age to Bronze Age (~4950-2600 cal BP) settlement named Alto do Castelo (Van Leeuwen and Janssen, 1985; Schattner, 1998). Local hydrology and vegetation may change not only as a response to changed Tagus fluvial activity. Factors like discharge of the local streams Rio Almonda and Vale de Atela, hampered downstream drainage possibilities and changed seepage flux, may cause local vegetation change which is not related to Tagus fluvial activity. Nonetheless, it is likely that—similar to large-scale lithological changes—synchronous large-scale local vegetation changes recognised at both sites reflect regional fluvial activity and/or environmental changes.

The vegetation at both sites shows a brackish environment at the base (Fig. 5.9) which persisted longer in the south due to gradual downstream migration of the fluvial system since ~7000 cal BP (Chapter 3). Since ~6750 cal BP, a freshwater fluvial environment was present in the Lower Tagus Valley, characterised by regular inundation. This period, lasting until ~5300 cal BP, became wetter towards the end. The following period until ~3250 cal

BP, is typified by regular inundation, punctuated locally by short intervals of drought and human impact (Fig. 5.9). At both sites the wettest period was between ~3250 and ~1500 cal BP, when permanently wet and open water environments existed and groundwater seepage was relatively strong. Towards the end of this period, regular inundation was registered again. At the onset of the final period (~1500 cal BP to present) human impact and regular inundations increased.

## 5.4 DISCUSSION

The synchronicity of lithological intervals at the two sites located ~18 km apart on both sides of the Tagus channel, implies a regional origin for the changes in fluvial activity since ~6500 cal BP (Figs. 5.4 and 5.5). Changes in fluvial activity may also be reflected in the local vegetation development. The local floodplain vegetation basically reflects the hydrological situation due to fluctuations in inundation frequency and groundwater level. By combining the reconstructed fluvial activity phases (Figs. 5.4 and 5.5) and the local vegetation development (Figs. 5.7 and 5.8) the Tagus flooding history and the potential impact of the vegetation cover on flooding can be established (Fig. 5.9).

### Fluvial activity and local vegetation

During Phase 1 (6500-5500 cal BP), fluvial activity was relatively high as deduced from relatively high mean clastic sedimentation rates (Figs. 5.4 and 5.5). This is reflected by the local vegetation, which indicates regular inundation and increasing wetness upwards (Fig. 5.9). The following Phase 2 (5500-4900 cal BP) with relatively low fluvial activity and increased organic deposition can not easily be correlated with local vegetation changes (Fig. 5.9). In Paul do Boquilobo the situation was permanently wet, while in Vale de Atela dry conditions prevailed. Possibly, decreased fluvial influence gives way to independent autogenic vegetation development at the two sites.

Phase 3 (4900-3500 cal BP), is characterised by relatively high fluvial activity and regular inundation in the Lower Tagus Valley (Figs. 5.4 and 5.5). However, local vegetation development shows relatively dry periods in Paul do Boquilobo. During this period Vale de Atela is dominated by anthropogenic activity with some periods with regular inundation (Fig. 5.9). The dominance of anthropogenic activity indicates relatively dry local circumstances, facilitating the agricultural use of the floodplain. This suggests that the local hydrological situation at the two sites was generally dry, despite increased Tagus (peak) flood discharges. This may be caused by a changed discharge regime with peak floods concentrated during the winter season when the floodplain was not

used for agriculture.

The gyttja and peat which accumulated during Phase 4a/b (3500-1000 cal BP) is interpreted as reflecting low fluvial activity with decreased Tagus (peak) flood discharges as confirmed by low mean clastic sedimentation rates (Figs. 5.4 and 5.5). However, during Phase 4a high groundwater levels prevailed at the studied sites as corroborated by the local vegetation development which reflects permanently wet conditions (Fig. 5.9). During Phase 4b permanently wet conditions persisted, although groundwater levels lowered in Paul do Boquilobo compared to Phase 4a. The low fluvial activity in the Lower Tagus Valley during Phase 4a/b is interpreted to reflect a discharge regime with less (peak) floods, possibly resulting from increased vegetation density due to the wetter circumstances. Increasing forest densities are known to lead to less peak floods and reduced sediment delivery (Keesstra, 2007).

During Phase 5 (1000-0 cal BP) highest mean clastic sedimentation rates at both sites were registered, reflecting high fluvial activity and higher (peak) flood discharges, probably resulting from deforestation (Chapter 4). This phase is reflected clearly in the vegetation development at both sites as a period with regular inundation and indications for human impact.

### **Fluvial activity and regional vegetation**

Since ~6000 cal BP regional tree pollen decreased in favour of shrub and herb pollen (Fig. 5.6). This reflects regional aridification and related regional forest decline combined with some human influence as previously identified in south Portugal and Spain (Carrión *et al.*, 2007; Fletcher *et al.*, 2007). The same regional forest decline was also found in northwest Spain, but there human deforestation played an increasing role since ~4000 cal BP (Van den Brink and Janssen, 1985; Van der Knaap and Van Leeuwen, 1995; Santos *et al.*, 2000). In general, during dry periods vegetation cover decreases, leading to less rainfall interception, lower soil water-holding capacity and higher slope erosion rates and increased (peak) flood discharge (e.g. Bosch and Hewlett, 1982; Hornbeck *et al.*, 1993; Sahin and Hall, 1996; Van Rompaey *et al.*, 2002; Lang *et al.*, 2003; Andréassian, 2004; Jordan *et al.*, 2005; Ward *et al.*, 2008).

Coinciding with the onset of regional forest decline, the African Humid Period ended (since 6000-5500 cal BP) as a result of gradually decreased summer insolation, leading to weakening of the African summer monsoon in the Mediterranean regions and regional drying (Claussen *et al.*, 1999; DeMenocal *et al.*, 2000; Renssen *et al.*, 2006; Naughton *et al.*, 2007). The coincidence between regional aridification, the progressive decline of regional forest and the end of the African Humid Period suggests a relationship between these events, which may have affected fluvial activity. However, the Lower Tagus Valley fluvial sedimentation history does not reflect these changes, because

the mean clastic sedimentation rate does not show a systematic increase in the studied sites (Figs. 5.4j and 5.5i).

On the other hand, quantitative estimates of Tagus sediment budgets for the Late Glacial and Holocene periods, indicate an increased sediment flux supplied to the estuarine and marine parts of the depositional system since ~7000 cal BP compared to the early Holocene (Chapter 6). An explanation for this apparent inconsistency may be that the sediment load of the river gradually increased, without a trend of increasing (peak) flood discharges registered in the distal floodbasin sites of Paul do Boquilobo and Vale de Atela. This situation was favoured by the conservatively maintained position of the Tagus channel, which was relatively deeply incised in its own floodplain (Chapter 3). Therefore, the increased sediment load was possibly directly transported to the downstream central tidal basin and offshore area, where it was deposited.

### Controls on fluvial activity

During the last ~1000 years, flood generation, duration and magnitude in Atlantic river catchments of the Iberian Peninsula were closely related to changes in winter precipitation (Rodrigo *et al.*, 1999; Benito *et al.*, 2003b). To evaluate the controls on fluvial activity during a large part of the Holocene, a comparison has been made of the Lower Tagus Valley fluvial activity phases with periods of increased fluvial activity and flood clusters in Spain and Tunisia (Fig. 5.10). Floodplain deposition is the result of a combination of *allogenic* (climatic, tectonic, eustatic and anthropogenic) and *autogenic* (intrinsic behaviour and complex response) controls. Although a strict distinction between allogenic and autogenic influenced phenomena can not simply be made because complicated interactions among these controls exist (Ethridge *et al.*, 1998; Bridge, 2003; Holbrook *et al.*, 2003; Stouthamer and Berendsen, 2007), the dominant allogenic controls are identified below.

The first phase of relatively high fluvial activity in the Lower Tagus Valley (6500-5500 cal BP; Phase 1), does not coincide with increased fluvial activity and flood-cluster records from Spain, possibly because only one slack-water deposit (5700 cal BP) was found (Benito *et al.*, 2003c; Thorndycraft and Benito, 2006b; Benito *et al.*, 2008). However, Phase 1 coincides with a peak of increased fluvial activity in Tunisia (Zielhofer and Faust, 2008) (Fig. 5.10). The increased fluvial activity during Phase 1 also coincides with the build-up of the southward thinning wedge of Tagus floodbasin deposits (FU-6B) across the underlying tidal deposits (Chapter 3). The build-up of the southward thinning wedge is interpreted as a direct response to the end of relative sea-level rise. Therefore, the relatively high fluvial activity during Phase 1 is the result of dominant relative sea-level control on overbank sedimentation.

Between 5500 and 4900 cal BP an episode with relatively low fluvial

**Figure 5.10** | Comparison of Lower Tagus Valley flood phases with fluvial activity from Tunisia and Spain.

activity occurred in the Lower Tagus Valley (Phase 2). This phase coincides with relatively low fluvial activity in Spain and Tunisia (Thorndycraft and Benito, 2006b; Zielhofer and Faust, 2008), suggesting a possible large-scale climatic control leading to less (peak) flood discharges (Fig. 5.10).

During Phase 3 (4900-3500 cal BP) increased fluvial activity was registered in the Lower Tagus Valley. The Lower Tagus Valley record and the Spanish and especially the Tunisian records show coinciding periods of increased fluvial activity (Fig. 5.10). Spanish records also show a cluster of slackwater flood deposits between 4820-4440 cal BP (Benito *et al.*, 2008). However, the Spanish and Tunisian records show temporally decreased fluvial activity between 4400 and 3800 cal BP, not coinciding with the Lower Tagus

Valley development (Thorndycraft and Benito, 2006b; Zielhofer and Faust, 2008). The coinciding periods of increased fluvial activity may be the result of a common large-scale climatic control. Nonetheless, the middle part of Phase 3 with high fluvial activity in the Lower Tagus Valley and low fluvial activity in Spain and Tunisia, implies that other controls or complex response processes (i.e. different rivers or river reaches respond differently or delayed to the same external control) are also active.

Phase 4a was characterised by accumulation of gyttja and peat with wet local circumstances and low Tagus fluvial activity (3500-2200 cal BP). During this wet phase, the 2800 cal BP event occurred in northwest Europe (Van Geel *et al.*, 1996). Simultaneously, wet conditions occurred in the Portuguese Serra da Estrêla (Van den Brink and Janssen, 1985; Van der Knaap and Van Leeuwen, 1995) and the northwest Spanish Lagoa Grande and Queixa Sierra (Santos *et al.*, 2000; Leira, 2005). The low fluvial activity in the Lower Tagus Valley during Phase 4a reflects a discharge regime with less (peak) floods, possibly resulting from increased vegetation density due to the wetter climatic circumstances. However, Spanish and Tunisian sites show high fluvial activity during this period and both slackwater and floodplain deposits registered flood clusters (Thorndycraft and Benito, 2006b; Benito *et al.*, 2008; Zielhofer and Faust, 2008) (Fig. 5.10). Because wet conditions were found in several Spanish and Portuguese sites, the wet conditions are probably the result of large-scale climatic control. However, high fluvial activity in Spain and Tunisia as opposed to low fluvial activity in the Lower Tagus Valley, suggests that other factors or complex response processes were controlling overbank sedimentation in the Lower Tagus Valley.

The wet conditions during Phase 4a were followed by less wet conditions (Phase 4b, 2200-1000 cal BP), with low fluvial activity in the Lower Tagus Valley (Fig. 5.10). This coincides partly with relatively low fluvial activity in Spain and Tunisia (Thorndycraft and Benito, 2006b; Zielhofer and Faust, 2008). Extensive soil formation occurred on the Lower Tagus Valley floodplain at the end of Phase 4b (Chapter 3), supporting relatively low fluvial activity. Because of similar low fluvial activity on the Iberian Peninsula and in Tunisia, Phase 4b is interpreted to reflect a period with common large-scale climatic control on fluvial activity.

Since ~1000 cal BP fluvial activity has been relatively high (Phase 5, Fig. 5.10), similar to the Spanish records (Benito *et al.*, 2003c; Thorndycraft and Benito, 2006b; Benito *et al.*, 2008). The increased fluvial activity during the last ~1300 years in Spain was mainly the result of human impact (Thorndycraft and Benito, 2006a, b). Similarly, the increased flooding in the Lower Tagus Valley is attributed to strong human impact on Tagus catchment vegetation (Chapter 4). According to Faust *et al.* (2004) the late Holocene fluvial

activity in northern Tunisia was chiefly driven by climate; human impact merely intensified or attenuated geomorphic processes. However, the strong effect of human impact (mainly deforestation) on fluvial activity in Spain and Portugal, suggests that increased human impact overruled climate as control on sedimentation in Iberian and Mediterranean regions.

Local floodplain-vegetation changes corroborate increased fluvial activity during Phases 1 and 5. Fluvial activity during these phases was primarily controlled by relative sea-level (Phase 1) and human impact (Phase 5). During Phases 2, 3 and 4b, local floodplain-vegetation changes and fluvial activity were negatively correlated, suggesting a disconnection between local vegetation development and fluvial activity. Because these phases coincide with periods of increased fluvial activity and flood clusters in Spain and Tunisia, they probably resulted from a large-scale control. It is therefore likely that fluvial activity during these phases was primarily controlled by climate. During Phase 4a local floodplain-vegetation and fluvial activity were also negatively correlated, however, local floodplain vegetation did reflect a wet regional climate, which was also found in other Portuguese and Spanish sites. Autogenic controls (e.g. floodplain vegetation filtering suspended sediment, levee height) and complex response processes may explain the discrepancy between the Lower Tagus Valley fluvial activity record and local floodplain-vegetation changes during Phases 2, 3 and 4a/b.

## 5.5 CONCLUSIONS

Due to continuous fluvial aggradation since ~6500 cal BP, the Lower Tagus Valley hosts a rare record of middle to late Holocene fluvial activity on the Iberian Peninsula. Two sites (Paul do Boquilobo and Vale de Atela) located ~18 km apart in distal, low-energy backswamps on both sides of the Tagus channel have registered the flooding history of the Tagus River. In these low-energy backswamps, fine-grained sediment layers which were deposited from suspended load of overbank flood water, reflect periods with multiple overbank floods. At both sites, synchronous lithological intervals accumulated, implying a regional origin for the changes in fluvial activity. Based on lithological changes, phases of high fluvial activity were identified between 6500-5500, 4900-3500 and 1000-0 cal BP and phases of low fluvial activity were identified between 5500-4900 and 3500-1000 cal BP.

Since ~6000 cal BP the regional forest declined progressively which is a sign of the regional drying trend which commenced after the end of the African Humid Period. However, this is not reflected by the Lower Tagus Valley flooding history which does not show systematic changes in sedimentation

rate and (peak) flood discharges.

Local floodplain vegetation registered alternating periods of wet, regularly inundated, dry and anthropogenically influenced conditions. Two out of five fluvial activity phases could clearly be linked with local floodplain-vegetation changes. During the other three phases autogenic controls and complex response processes probably caused the discrepancy between fluvial activity phases and local floodplain-vegetation changes.

A comparison between the Lower Tagus Valley flooding history and phases of fluvial activity in Spain and Tunisia shows that the dominant allogenic controls of fluvial activity in the Lower Tagus Valley were relative sea level (6500-5500 cal BP), climate (5500-1000 cal BP), and human impact (1000-0 cal BP). The results of the present study show that the fluvial archive as a record of environmental change is complex, as a result of the plethora of processes active in the fluvial realm.

# CHAPTER 6

Sediment volume estimates are fundamental for understanding sea level, tectonic and climatic controls of sedimentation patterns in source-to-sink fluvial systems at continental margins. Here we

## Last glacial to recent sediment fluxes in the Tagus fluvial-marine system

present the first quantification of the migration of sediment depocenters of a major river on the Iberian Peninsula under conditions of rapid relative sea-level rise and climatic aridification since the end of the African Humid Period. The Tagus depositional system was studied using a dataset of terrestrial and marine cores covering the period since 18,000 cal BP. The quantitative estimates of sediment volume through time show that in different parts of the Tagus fluvial-marine depositional system: (1) during low relative sea level in the last glacial period, sediment bypassing favoured sedimentation on the Tagus Abyssal Plain; (2) during relative sea-level rise the main sediment depocenter shifted towards the shelf, where it arrived at 13,500 cal BP, and soon after the main depocenter migrated to the Lower Tagus Valley at about 12,000 cal BP; and (3) during high relative sea level, the main depocenter was located in the Lower Tagus Valley with a dramatic higher (up to 2.5 times) sediment flux and storage, favoured by more arid climate conditions, and land-use changes. Our study indicates that future erosion rates will intensify even further as a result of the predicted increase in arid conditions on the Iberian Peninsula, in line with modelling results.

## 6.1 INTRODUCTION

Studies of sediment depocenter migration in late Quaternary fluvial-marine depositional systems provide thorough insights in sea level, tectonic and climatic controls, but often lack a quantitative approach (Blum and Törnqvist, 2000; Sommerfield and Lee, 2004). Here we present a new quantitative approach for assessing the migration of depocenters of a large fluvial-marine sediment dispersal system on the Iberian Peninsula for the period since 18,000 cal BP. The Iberian Peninsula has witnessed aridification since the mid Holocene (Magny *et al.*, 2002), and the large Tagus fluvial-marine system on the Iberian passive margin was strongly controlled by relative sea-level (RSL) change (Chapter 3).

We used an extensive dataset of sedimentological and palynological data derived from 385 terrestrial and 11 marine cores with a well calibrated chronology based on 127 radiocarbon dates (Fig. 6.1). Valley-fill history and

**Figure 6.1** | Location map of the Lower Tagus Valley (LTV), Tagus shelf and Tagus Abyssal Plain: (A) Tagus catchment and study area on the Iberian Peninsula; (B) terrestrial and marine cores and isopach map of sediments deposited in the LTV and on the shelf since ~12,000 cal BP. The narrow bedrock-confined LTV enables robust sediment pathway and volumetric reconstructions. Buried submarine valleys from Mougénot (1985), bathymetry from IOC, IHO and BODC (2003) and INETI/DGM.

palaeogeography of the Lower Tagus Valley show an erosive system until ~14,000 cal BP, followed by a retrograding system until ~7000 cal BP. A maximum flooding surface was established followed by a prograding system. Sediment budgets across the Tagus fluvial-marine system were quantified for the last 12,000 cal BP, using the volume of fluvial and marine deposits. During the preceding period the shelf was exposed subaerially due to the low RSL, and sediments were transferred to the deep sea, hampering volumetric calculations. The aridification since the mid Holocene may have caused changes in sediment production in the catchment.

## 6.2 METHODS

Sediment volumes were quantified using spatial models generated in Petrel 2008 software (Schlumberger Ltd.). Three-dimensional surfaces were modelled using convergent (geo-statistical) interpolation. For volumetric modelling, every  $90 \cdot 90$  m grid cell was multiplied by the height between the upper and lower surface. Because the average carbonate and organic content of the sediments is below 5 %, no correction for volumetric calculation was made. Sediment volumes for the Tagus depocenters were converted to mass using dry bulk density. The sensitivity of storage rates to changes in dry bulk density of  $\pm 0.1 \text{ t/m}^3$ , reaches up to  $\pm 8 \%$ .

Terrestrial cores (385) and radiocarbon ages (86) from the Lower Tagus Valley (LTV), and detailed reconstructions of valley-fill history and palaeogeography, form the basis for the definition of terrestrial depocentre size and timing of deposition (De Mendonça, 1933; Van Leeuwen and Janssen, 1985; LUSOPONTE, 1995; Ramos *et al.*, 2002; Ramos Pereira *et al.*, 2002; BRISA, 2005; Azevêdo *et al.*, 2006; INETI, 2007; Van der Schriek *et al.*, 2007b; Chapters 3 and 4).

We used 11 marine cores and 41 marine radiocarbon ages (Labeyrie and Turon, 2005a, b; Segl and Alt-Epping, 2005a; Abrantes *et al.*, 2008). In this study we present one core recovered from the Tagus shelf (D13882) (Weaver, 2003) and one from the landward limit of the Tagus Abyssal Plain (TAP) (MD03-2698). The marine radiocarbon ages (Table 6.1) were calibrated using the program CALIB v5.0 (Stuiver and Reimer, 1993; Stuiver *et al.*, 2005) and the Marine04 age calibration data from Hughen *et al.* (2004). The marine calibration incorporates a time-dependent global ocean reservoir correction of about 400 years. Abrantes *et al.* (2005) proved that this is a good estimate for marine material off Portugal for the last ~110 years; however, older dated material may have been affected by different conditions. Therefore and to correct for local variations, the difference in reservoir age of the

study area and the global ocean was determined ( $\Delta R = 262 \pm 164$  y) using the marine reservoir correction database of Stuiver and Braziunas (1993). All mentioned radiocarbon dates are expressed as calibrated calendar ages (cal BP) with age spans at the  $2\sigma$  range.

Grainsize was measured using a Fritsch A22 Laser Particle Sizer following the methods described by Konert and Vandenberghe (1997). The marine cores contained little opal; this opal was not removed. Grainsize samples of core D13882 (94) were taken every 5 cm in the upper 4 m and every 20 cm in the rest of the core. Grainsize samples in core MD03-2698 (40) were also taken at 20 cm intervals, avoiding turbiditic layers.

Pollen samples were prepared according to Faegri and Iversen (1975); clastic material was removed using a sodium polytungstate heavy liquid separation. Pollen concentrations were calculated based on added *Lycopodium* marker spore tablets (Stockmarr, 1971). The ratio of fossil pollen to marker spores was calculated using:  $C = (T \cdot X_{\text{TAB}} \cdot P) / (X \cdot S)$  where: C is the concentration of fossil pollen grains/cm<sup>3</sup>; T is the number of added tablets;  $X_{\text{TAB}}$  is the number of marker spores per tablet; P is the number of fossil pollen grains counted; and S is the volume of the sediment sample in cm<sup>3</sup>. Pollen concentration was calculated based on all pollen and spores in a sample, excluding *Pinus* pollen.

From 11 sand samples from the LTV (ca. 100 cc), the heavy mineral composition (53–420  $\mu\text{m}$ ) was determined based on a minimum count of 100 transparent grains per sample.

## 6.3 DEPOCENTERS AND SEDIMENT VOLUMES

### Tagus Abyssal Plain (TAP)

During low RSL, Tagus sediments bypassed the continental shelf and slope and were transported as turbidites through the Cascais and Lisbon-Setúbal Canyons to the vast Tagus Abyssal Plain (Fig. 6.1), where turbidite sediments alternate with pelagic beds (Lebreiro, 1995; Alves *et al.*, 2003). Although deposition of turbidites abruptly ended ~15,000 cal BP (Fig. 6.2a), the sedimentation rate remained relatively high on the abyssal plain until ~11,500 cal BP (~1.3 mm/y, Fig. 6.2d). This high rate reflects a continued strong supply of fluvially derived sediment to the abyssal plain due to efficient sediment bypassing through the canyons during low RSL, as also shown by the high pollen concentration (Fig. 6.2c). Because pollen grains behave as fine-grained sediment (Chmura and Eisma, 1995), the pollen concentration can be considered as a proxy for the ratio of terrestrial to marine sediment input. Pollen were mainly supplied by the Tagus River, and aeolian supply was limited (Naughton

**Figure 6.2** | Marine core MD03-2698 from the Tagus Abyssal Plain ( $\sim 4602$  m;  $38^{\circ}14'$  N -  $10^{\circ}23'$  W): a) lithology with calibrated radiocarbon ages ( $2\sigma$ ); b) grainsize distribution; c) pollen concentration, high concentration = high sediment supply (analyses: Esther Bootsma); and d) average sedimentation rates. These sandy turbidites are mineralogically similar to LTV sands, confirming their fluvial origin (Duplaix *et al.*, 1965).

*et al.*, 2007). Around 11,500 cal BP sediment bypassing came to a halt, resulting in a six fold decrease in sedimentation rate (from  $\sim 1.3$  to  $\sim 0.2$  mm/y). The pollen concentrations in the sediments are five times lower than during the preceding period and are carbonate-rich (40-70 %), implying little sediment transfer to the deep sea during rising and high RSL (Fig. 6.3).

### Tagus shelf (subaqueous delta and mudbelt)

Sedimentation on the continental shelf started at  $\sim 13,500$  cal BP with a high initial sedimentation rate ( $\sim 2.6$  mm/y) during the pre-Holocene period (Fig. 6.4d). A sandy interval which was deposited in the early stage of the Holocene ( $\sim 10,500$ -5000 cal BP) coincides with the maximum flooding surface. This interval results from a period when fluvial mud was mainly trapped in the Lower Tagus Valley and mud supply to the shelf was low, making winnowing

**Figure 6.3** | Location of depocenters on the Iberian margin for the last 18,000 cal BP with respect to relative sea level (RSL). The main depocenter shifted due to RSL rise from the Tagus Abyssal Plain (TAP) to the Tagus shelf. Shortly after 12,000 cal BP, the landward shift to the Lower Tagus Valley (LTV) occurred and tidal, marine and fluvial sediments were deposited. The effect of winnowing on the shelf was strong when sediment supply was low (see text). After the end of RSL rise, the LTV progressively filled and export to the shelf started and was amplified during the last ~2000 cal BP by human land-use changes. MFS = maximum flooding surface.

by bottom currents relatively most effective relative to the preceding period (Chapter 4). This caused a low sedimentation rate on the shelf of ~0.3 mm/y (Fig. 6.4d). The low sedimentation rate and low fluviially derived mud input are also shown by the lowest pollen concentration (Fig. 6.4c). Around 5500 cal BP, the sedimentation rate increased (~1.2 mm/y) due to an enhanced supply of terrestrial material to the shelf, as shown also by an up to eightfold increase in pollen concentration. This reflects decreased sediment trapping in the Lower Tagus Valley, and mudbelt deposition on the shelf. The strong increase in sedimentation rate since ~2000 cal BP may reflect catchment deforestation.

The volume of sediment deposited on the Tagus shelf between 12,000 and 7000 cal BP is probably relatively small and much deposition on the shelf already occurred before 12,000 cal BP (Fig. 6.4a). Unfortunately, no data are

**Figure 6.4** | Marine core D13882 from the Tagus shelf (-87 m; 38°38' N - 9°27' W): a) lithology with calibrated radiocarbon ages ( $2\sigma$ ) (*italic* ages are considered too old due to reworking); b) grain size distribution; c) pollen concentration, high concentration = high sediment supply (analyses: Martine Hagen); and d) average sedimentation rates. available to quantify the dimensions of the pre-7000 cal BP sediment body. Therefore, the volumetric calculations of the related shelf sediment body were performed for the period after 7000 cal BP, when the subaqueous delta (Fig. 6.1) and mudbelt had formed (Mougenot, 1985; Chapter 3). The subaqueous-delta volume was calculated using the reconstructed bathymetry of 7000 cal BP as the basal surface and by taking the present-day bathymetry as the upper surface. The mudbelt was considered to be an outward thinning, low-gradient ridge (cf. Jouanneau *et al.*, 1998). However, poorly constrained morphological boundaries and diffuse sediment dispersal in the marine realm complicate calculation of shelf volumes. Despite the narrow shelf, most sediment probably remained on the shelf (Jouanneau *et al.*, 1998), constraining the functioning of the post-7000 cal BP depocenter as a trap for fluvially derived sediment. Our calculations show that the subaqueous delta contains ~5.5 km<sup>3</sup> of sediment and the mudbelt ~0.7 km<sup>3</sup> (Fig. 6.1, Table 6.2). The relatively small

volume of mudbelt sediments shows that exclusion of the pre-7000 cal BP deposits has a minor impact on the sediment budget, although it may have caused a limited underestimate of the total 12,000-7000 cal BP sediment volume.

### Lower Tagus Valley (LTV)

Since ~12,000 cal BP, rising RSL caused drowning of the deeply incised Lower Tagus Valley (Fig. 6.5), which accommodates up to 70 m of sediment. Heavy mineral analysis of Lower Tagus Valley sands confirms a fluvial provenance without a significant contribution of marine sediments (Fig. 6.6). The basal lowstand topography was dated at about 12,000 cal BP and is based on the study of 283 drilled cores and palaeogeographic interpretation (Chapter 3). The maximum flooding surface dates to 7000 cal BP based on 12 radiocarbon ages, and it's position is also based on palaeogeographic interpretation (Chapter 1). The upper surface equals the present-day topography. This shows that since 12,000 cal BP a total volume of ~20.4 km<sup>3</sup> of sediment has accumulated in the Lower Tagus Valley (Fig. 6.1, Table 6.2).

The maximum flooding surface was used to calculate differences in sediment supply between the retrograding and prograding systems. In the north the Lower Tagus Valley is narrow and shallow and the maximum flooding surface is well defined. In contrast, further downstream the valley widens and deepens and less data are available to precisely locate the surface. Nonetheless, in the south a tidal basin was present with a relatively flat bottom, facilitating a careful and reliable interpolation of the maximum flooding surface. Our results show that about 13.9 km<sup>3</sup> of sediment accumulated between the maximum flooding surface and the present-day topography. Subtracting this value from the total Lower Tagus Valley sediment volume (20.4 km<sup>3</sup>) reveals that the total volume deposited between 12,000 and 7000 cal BP is ~6.5 km<sup>3</sup>.

## 6.4 DISCUSSION AND CONCLUSION

### Depocenter migration

During the Last Glacial Maximum, sedimentation in the Lower Tagus Valley and on the exposed shelf was limited. Although lowstand RSL remained ~30 m above the shelf break, fluvial sediments bypassed the shelf via incised valleys directly funnelling into the heads of marine canyons (Fig. 6.1). Bypassing of fluvial sediment to the deep sea resulted in high-frequency turbidite deposition (up to 10 turbidites per 500 y) near the Tagus Abyssal Plain between 20,000 and 15,000 cal BP (Fig. S1, Lebreiro *et al.*, in press). During low RSL conditions, turbidites delivered ~35 km<sup>3</sup> of sediment to the Tagus Abyssal

**Figure 6.6 |** Heavy mineral composition of 11 Lower Tagus Valley samples. Samples were taken from cores and are arranged from old (left) to young (right). FU-codes refer to facies units (Chapter 3) and depth is relative to surface. No large changes in heavy mineral composition are present, confirming a single upstream (fluvial) sediment source. The two oldest samples were taken from lowstand deposits and possibly suffered from long-term exposure and soil weathering.

Plain every 10,000 cal BP (Weaver *et al.*, 2000), which is considerably more than the total sediment volume deposited on the Tagus shelf and in the Lower Tagus Valley during the last 12,000 cal BP (26.6 km<sup>3</sup>, Table 6.2). This suggests that the Iberian terrestrial sediment flux during glacial periods with low RSL was noticeably higher than during interglacials.

The end of turbidite deposition at about 15,000 cal BP reflects the RSL rise after the Last Glacial Maximum (Fig. 6.3). Simultaneously, the Tagus changed from a braided into a single-channel river, due to climate change and increased production of fine-grained sediment. Until ~11,500 cal BP siliciclastic hemipelagic sedimentation on the Tagus Abyssal Plain caused a high sedimentation rate due to the continued supply of fluvially derived sediment. The final stage of rapid abyssal plain deposition (15,000-11,000 cal BP) coincides with the onset of increased shelf sedimentation at 13,500 cal BP (Fig. 6.4). Deposition on the Tagus Abyssal Plain decreased strongly since ~11,500 cal BP, reflecting a landward depocenter shift (Fig. 6.3).

Rising RSL created accommodation space in the Lower Tagus Valley, which caused fluvial aggradation since ~12,000 cal BP, soon followed by transgressive tidal and shallow marine sedimentation (Figs. 6.3 and 6.5). Increasing sediment volumes were trapped in the Lower Tagus Valley, strongly reducing export to the shelf. Here, winnowing efficiently removed the finer-grained fractions, leaving a sandy unit deposited at ~7000 cal BP (Fig. 6.4). Until about 7000 cal BP, the depocenter shifted landward when Lower Tagus Valley accommodation space was maximal.

The end of RSL rise is marked by the maximum flooding surface, the onset of bayhead delta progradation in the Lower Tagus Valley, and the build-up of a fluvial wedge (Chapter 3). Around 7000 cal BP, the valley was filled to such an extent ( $6.5 \text{ km}^3$ , Table 6.2) that gradually sediment export increased again. This caused a progressive seaward build-up of the subaqueous delta and mudbelt and shift of the depocenter (Fig. 6.3). Since 7000 cal BP, the Lower Tagus Valley and shelf depocenters accommodated  $20.1 \text{ km}^3$  of sediment (Table 6.2). Increased deposition in the fluvial valley and on the shelf since ~2000 cal BP is likely to be caused by land-use changes in the Tagus catchment.

Our model of depocenter migration of a portion of the Iberian passive margin provides a unique example for comparative studies of Quaternary systems worldwide. Glacial sediment transfer to the abyssal plain was strong despite a RSL lowstand which remained ~30 m above the shelf break. This is in contrast to regions where the absence of incised valleys and canyons caused physical disconnection between continental and deep sea environments (Törnqvist *et al.*, 2006). During RSL highstand, sediment fluxes to the deep sea were strongly limited due to accommodation in fluvial and shallow marine depocenters. This strongly limited the offshore sediment export, despite a narrow continental shelf. Marine palynological studies on the Iberian margin (e.g. Hooghiemstra *et al.*, 1992) should therefore take migrating depocenters into account.

### Calculation of sediment fluxes

Storage rates were calculated to identify changes in sediment flux (Table 6.2). Comparison of the total storage rates of  $1.6 \cdot 10^6 \text{ t/y}$  (12-7 ka) and  $4.0 \cdot 10^6 \text{ t/y}$  (7000-0 cal BP) shows that the latter is up to ~2.5 times higher. When comparing the storage rates of the Lower Tagus Valley deposits for the two above mentioned periods, the storage rate since 7000 cal BP is ~1.7 times higher than during the preceding period (Table 6.2), despite the omission of pre-7000 cal BP shelf sediments from the volumetric calculations. This supports a strong sediment-flux increase. Because some suspended sediment escaped from the system due to coastal and marine currents during both periods (as shown by the presence of clay in the Holocene section of the Tagus Abyssal Plain core),

the storage rates represent minimum values for Tagus sediment flux.

A climatic effect may explain the increased sediment flux. The African Humid Period ( $\sim 11,500$ - $5500$  cal BP) ended due to the gradually decreasing summer insolation, leading to weakening of the African summer monsoon in the Mediterranean and North Africa (Claussen *et al.*, 1999; DeMenocal *et al.*, 2000). On the Iberian Peninsula this led to regional aridification and a progressively decreasing forest cover, resulting in increased herbaceous vegetation (Carrión *et al.*, 2007; Fletcher *et al.*, 2007). The more open vegetation cover increased vulnerability to soil erosion and thus Iberian fluvial sediment yields increased, leading to floodplain aggradation (Thorndycraft and Benito, 2006). The similar timing of the weakening of the summer monsoon, decreasing forest cover, increasing sediment yields, and up to  $\sim 2.5$  times higher Lower Tagus Valley and shelf sediment fluxes, implies a causal relationship between the above observations.

Besides climate, a large part of the increased storage rate is the result of increased human impact during the last  $\sim 2000$  cal BP, as tripled sedimentation rates are considered to be caused by land-use changes (Chapter 4). The  $\sim 2.5$  times higher sediment flux is explained by a combination of climatic and human impact during the last 7000 cal BP, whereby during the last  $\sim 2000$  cal BP climatic influence was overwhelmed by land-use changes.

### **Denudation rates and implications for future intensity of erosion**

To validate the sediment volumes and to provide a starting point for future catchment erosion studies, we divided the total annual average sediment mass ( $3.6 \cdot 10^{13}$  kg/ $12,000$  y =  $3.0 \cdot 10^9$  kg/y) deposited in the Lower Tagus Valley and shelf sediment depocenters by the Tagus catchment area ( $\sim 8 \cdot 10^4$  km<sup>2</sup>), yielding  $\sim 3.7 \cdot 10^4$  kg/km<sup>2</sup>/y. Using an average rock density of 2700 kg/m<sup>3</sup>, this specific sediment yield was converted into a net mechanical denudation rate of  $\sim 0.014$  mm/y (cf. Hovius, 1998). This is a minimum estimate of catchment denudation rate, since a large fraction of sediment eroded on slopes is stored in colluvial, alluvial fan and fluvial deposits and currently does not reach the Lower Tagus Valley and shelf sediment depocenters. If we assume that 15 % of the sediment eroded on slopes in the catchment reaches the downstream depocenters, and recalculate mechanical denudation rate using an estimated total eroded catchment sediment mass of  $\sim 20.0 \cdot 10^9$  kg/y, total mechanical denudation rate equals  $\sim 0.09$  mm/y. This value is in agreement with long-term (10,000-40,000 years) erosion rates from middle European catchments, which range between 0.02 and 0.1 mm/y (Schaller *et al.*, 2001).

Although the average denudation rate is in agreement with those of other European rivers, the post-7000 cal BP denudation rate was up to  $\sim 2.5$

times higher than during the pre-7000 cal BP period. Given the predicted tendency towards decreasing mean seasonal rainfall over the Iberian Peninsula (Goodess and Jones, 2002), and the increase of extreme events of flooding and drought in the next century (Lehner *et al.*, 2006), our study indicates that future erosion rates will intensify even further on the Iberian Peninsula.

# CHAPTER 7

## Synthesis

This chapter synthesises the sedimentary development and controls of the Tagus fluvial-marine depositional system since the Last Glacial Maximum (~ 20,000 cal BP).

## 7.1 PALAEOGEOGRAPHY AND DEPOCENTRES

### **Around 20,000 cal BP | lowstand relative sea level: incision**

At around 20,000 cal BP relative sea-level lowstand ( $\sim 120$  m below present-day sea level) caused deep incision ( $\sim 70$  m near Lisbon) by the Tagus River (Chapter 2 and 3). The effect of incision was registered far inland (up to  $\sim 100$  km). This is the result of a direct connection between the Lower Tagus Valley and the ocean across the narrow ( $\sim 30$  km) continental shelf. Despite the fact that lowstand sea level remained  $\sim 30$  m above the shelf break, fluvial sediments were efficiently bypassing the largely exposed shelf via incised valleys directly funnelling into the heads of marine canyons and to the Tagus Abyssal Plain, where the main depocentre was located (Chapter 6). Bypassing of fluvial sediment to the deep sea resulted in strong turbidite deposition on the Tagus Abyssal Plain between 20,000 and 15,000 cal BP. Around that time, the Tagus was a braided, high-gradient ( $\sim 60$  cm/km) river which was probably a sediment conveyor-belt fluvial system, rather than an aggrading system, as testified by the relatively small thickness (10–15 m) and large width of the lowstand fluvial gravels (Chapters 2 and 3). The deep incision of the Lower Tagus Valley and the efficient sediment bypass, show that besides catchment size (upstream control) and sea level (downstream control) the width of the shelf is an important downstream control on incision depth and width through fluvial gradient and landward extent of regressive erosion.

### **20,000–12,000 cal BP | rapid sea-level rise: transgression**

A gradually moister and warmer climate since  $\sim 20,000$  cal BP caused the change from a braiding to a single-channel fluvial system at around 14,000 cal BP, which deposited fine-grained aggrading fluvial overbank deposits in the deeply incised Lower Tagus Valley (Chapter 2 and 3). Shortly after this ( $\sim 12,000$  cal BP), relative sea-level rise rapidly pushed the single-channel fluvial system inland, leading to upstream migration of the long profile crossover, creation of accommodation space and ultimately the drowning of the Lower Tagus Valley. The single-channel fluvial overbank deposits were found only locally, probably because they accumulated in a narrow, deeply incised valley, which was cut during the 30,000–20,000 cal BP relative sea-level drop within the broad fluvial plain (Chapter 2). The non-erosive transition to tidal deposits in the top of the fine-grained lowstand deposits indicates that the overbank deposits were preserved remarkably well. This is due to the rapid relative sea-level rise and transgression, precluding marine erosion. The lowstand braided and single-channel river deposits are part of the lowstand systems tract (Chapter 2).

On the Tagus Abyssal Plain rapid sedimentation continued until ~11,500 cal BP, because of a continued supply of fluvially derived sediment. The final stage of rapid abyssal plain deposition coincides with the onset of increased sedimentation on the shelf at around 13,500 cal BP, which continued until ~10,500 cal BP and reflects a landward depocentre shift caused by relative sea-level rise (Chapter 6).

### **12,000-7000 cal BP | final stage of sea-level rise: transgression**

This period is characterized by the final stage of relative sea-level rise from 40 m below present-day sea level around 12,000 cal BP to present-day sea level at around 7000 cal BP (Chapter 3). As a result, the deeply incised lowstand valley was transgressed by tidal and marine environments and around 7000 cal BP the Lower Tagus Valley was completely drowned and occupied by a transgressive tidal environment which reached up to 100 km inland. This transgressive tidal environment reflects the transgressive systems tract (Chapter 2). The Lower Tagus Valley trapped increasing sediment volumes, which limited export to the shelf. This resulted in strongly decreased sedimentation on the shelf during the early stage of the Holocene (~10,500-5000 cal BP) (Chapter 6). Until around 7000 cal BP, the depocentre shifted landward because accommodation space was maximal in the Lower Tagus Valley. The morphology of the Lower Tagus Valley with its narrow exit created a sheltered inland basin upstream of Lisbon. The narrow exit strongly reduced the effect of storms and storm surges in the drowned valley, creating a relatively quiet environment on a wave-dominated Atlantic Coast. This quiet environment together with the depth of the incision facilitated deposition of fine-grained prodelta deposits and prohibited the import of coastal sand (Chapters 2 and 3).

### **7000-2000 cal BP | fluvial sediment supply: regression**

Relative sea-level stability since 7000 cal BP resulted in regression marked by bayhead delta progradation and the build-up of a fluvial wedge in the Lower Tagus Valley, representing the highstand systems tract (Chapter 2). Around 5000 cal BP, the valley was filled to such an extent that gradually sediment export occurred again, and on the shelf a subaqueous delta and mudbelt built up, reflecting a seaward depocentre shift (Chapter 6). Due to continued fluvial sediment supply after the end of the relative sea-level rise (~7000 cal BP) combined with the protected setting, regression was mainly upstream controlled. The resulting fluvial sediment wedge prograded downstream and simultaneously the Holocene onlap point migrated upstream. The flooding history of the last ~6500 years in the Lower Tagus Valley was dominantly controlled by climatic changes during the period between 5500 and 1000 cal BP (Chapter 5).

## **2000-0 cal BP | human impact: increased fluvial-marine sedimentation**

Since ~2000 cal BP an increasing sedimentary response of the Tagus fluvial-marine depositional system to land-use changes in the catchment was registered (Chapter 4). In the floodplain grainsize coarsened and sedimentation rate and magnetic susceptibility increased during this period. This is explained by increased erosion of catchment slopes due to deforestation and increasing agriculture, which led to an increased flooding frequency and/or intensity. On the Tagus shelf the mudbelt grainsize fined, together with a higher sedimentation rate and increased magnetic susceptibility. The fining grainsize is a consequence of an increased suspended sediment flux towards the shelf. The higher concentration of fine mud may have resulted in subdued winnowing and therefore a better preservation of fine-grained sediment. Four depositional phases linked with anthropogenic impact on the natural landscape in the Tagus catchment were identified (~2300/~1600/~1100/~670 cal BP), the latter two being the strongest ones. Since land-use changes like deforestation and agriculture in the Tagus catchment caused increased runoff, offshore proxy records should be interpreted with caution with respect to climatic changes for the last few thousand years.

## **7.2 CONTROLS**

The multi-disciplinary and multi-proxy approach utilized in the present study has clearly demonstrated the shelf region—being at the confluence of terrestrial and marine processes—to be extremely sensitive to developments in the terrestrial and marine realms. The detailed study of sediment depocentres migrating from the deep-marine abyssal plain to the inland river valley and seaward again has shown to be of great value for the explanation of sedimentary successions on the continental shelf.

### **Sea-level change**

Sea-level change has a strong control on shifting sediment depocentres. Depocentre movement and sea-level change play a large role in the situation of large sediment bodies such as fluvial channels and turbidites, which are potential hydrocarbon reservoirs. Depocentre movement and sea-level change also affect pollen concentrations in marine sediments. To deal with this, marine palynological studies should take into account palaeogeography and the position of sea level relative to the shelf break, to better understand the sediment and pollen source.

## Configuration of the continental shelf

The configuration of the continental shelf (narrow, incised by a river valley) greatly affects sediment transport and bypass to the deep sea, thereby affecting depocentre location. A deeply incised inland river valley captures large sediment quantities during sea-level highstand, thereby limiting marine deposition. On the other hand, a deeply incised valley funnelling into the head of a submarine canyon efficiently bypasses sediment to the deep sea during sea-level lowstand.

## Human impact

Using detailed sedimentological, chronological and historical data from the river valley and shelf, the effect of human impact in the river catchment could be traced from source-to-sink. The extensive human impact thereby shed light on the direction, scale and time of the response of a fluvial-marine depositional system to large-scale external forcing.

## Tectonic activity

The studied region is known to be tectonically active, as illustrated by large historic earthquakes in 1531, 1755 and 1909 AD. Despite this historic tectonic activity, the horizontal relative sea-level curve since ~7000 cal BP proves that neotectonic uplift or subsidence were limited. Further, the present study has not identified sedimentological features in the fluvial-marine depositional system which could be clearly linked with earthquakes or tsunamis. The lowstand braided Tagus River deposits are relatively thin (up to 15 m thick) and directly overly Tertiary deposits in the Lower Tagus Valley. This implies that subsidence in the Lower Tagus Valley was absent during the Quaternary period and suggests that long-term tectonic uplift occurred, preventing the deposits from being lowered below the scour depth of younger fluvial systems.

## Fluvial sediment supply and climate change

Relative sea-level stability since 7000 cal BP resulted in the increased relative importance of fluvial sediment supply, which controlled regression and fluvial progradation (Chapter 3). Quantitative estimates of sediment volume for the last ~12,000 years show a dramatically increased sediment flux and storage in the Tagus fluvial-marine depositional system after ~7000 cal BP, which was favoured by climate change. Since the end of the African Humid Period (~5500 cal BP) climate resulted in more arid conditions, followed by a progressive decrease of regional forest cover. Added to this are land-use changes during the last ~2000 years. These changes caused an increased vulnerability to soil erosion in the Tagus catchment and an up to a 2.5 times higher sediment flux to the Lower Tagus Valley and shelf, when compared to the pre-7000 cal BP

period (Chapter 6). It is striking that the increased sediment flux was not coinciding with a gradual increase in (peak) flood discharges during the last ~6000 years although three phases of increased fluvial activity were established in distal floodbasin settings (6500-5500, 4900-3500 and 1000-0 cal BP) (Chapter 5). Quantitative estimates of sediment volume deposited in the Tagus fluvial-marine depositional system have enabled calculation of the total mechanical denudation rate for the Tagus catchment, which equals ~0.09 mm/y (Chapter 6). This value is in agreement with long-term (10-40 ka) erosion rates from Central European catchments.

### **Sediment budgets at a passive continental margin**

The present study uses for the first time a (semi-) quantitative approach to quantify sediment fluxes and budgets of a fluvial-marine depositional system. This study identified an increased flux and storage of sediment during the last ~7000 years, despite the fact that this was not identified by the analysis of the flooding history of the river using local observations (cores). This illustrates the advantage of a (semi-) quantitative approach using sediment budgets, because it provides a time-integrated three-dimensional reconstruction of sediment supply and deposition. Local differences in sedimentation which are inherent with different depositional environments have a limited effect on a reconstruction based on sediment budgets. Further, sediment budgets provide a powerful tool to link erosion with deposition, to identify changes in time and to link land and ocean depocentres. This is essential because changing external controls affect the complete depositional system. This underlines the importance of an integrated land-ocean study and the quantification of fluvial-marine sediment fluxes to identify effects of e.g. climate change and human impact on depositional systems.

## **7.3 FUTURE RESEARCH**

Although this thesis contributes to a better understanding of fluvial and marine deposition on a passive continental margin, questions that remain to be answered are:

1. *How do fluvial and marine deposition on a passive continental margin develop on timescales of hundred thousands of years?* The present study only covers the last ~20,000 years, whereas sea level, climate, tectonics and sediment production on larger time-scales have varied considerably and probably interacted in much different ways. While marine records are known to represent millions of years, problematic for such a study will be the lack of terrestrial data due to erosion. Process-based catchment modelling under different scenarios of boundary conditions will be indispensable to understand developments occurring on land. Due

to the narrow exit near Lisbon, the Tagus River acts as a point-source of sediment, which together with the large sediment supply, makes this river well suited for this type of study.

2. *How are vegetation and sediment production affected by climatic aridification and what is the response of a fluvial system to this?* Although the present study suggests a relationship between the end of the African Humid Period, subsequent aridification and forest decline on the Iberian Peninsula and an increased sediment flux, the exact mechanisms linking climatic aridification to changing sediment fluxes in the fluvial and marine realm are unclear. For example, attention should be given to the buffering effect of colluvial, alluvial fan and inland fluvial basins.
3. *How have sediment fluxes and budgets evolved on smaller time-scales?* As the present first-order quantification of sediment volumes has highlighted major differences between the pre and post-7000 cal BP periods, a more detailed study would greatly add to the understanding of cause-and-effect relationships and response times. This requires a more detailed chronology, using radiocarbon dating.
4. *What is the detailed postglacial relative-sea level history in the south-west of the Iberian Peninsula and what were the local factors controlling relative sea-level change?* The relative sea-level reconstruction from the present study shows an early Holocene rising limb of the curve which plots above eustatic sea level reconstructions from tectonically stable regions elsewhere. At around 7000 cal BP relative sea-level rise reached the present-day level and remained stable since that time. This suggests at least early Holocene tectonic uplift, and possibly also uplift after 7000 cal BP. The resolution of the presented relative sea-level reconstruction limits the ability to answer this question and therefore a more detailed study of postglacial relative sea-level rise is needed.
5. *What is the applicability of magnetic susceptibility measurements for stratigraphic correlation in terrestrial-marine environments?* In this study the magnetic susceptibility signal has been used as a tool to correlate terrestrial and marine sediments. Increased magnetic susceptibility values have been interpreted as a proxy for soil erosion. Only the basic “volume-based magnetic susceptibility” was used and no magnetic measurements from catchment sediments and soils were done. Therefore a study of the value of the different magnetic properties that can be measured on terrestrial and marine sediments and their applicability in linking erosion from catchment slopes with downstream deposition is needed.
6. *What is the effect of future climate change on water and sediment discharge of the Tagus River?* For the next century a tendency towards

decreasing mean seasonal rainfall over the Iberian Peninsula and increasing extreme events of flooding and drought is predicted. Our study indicates that future erosion rates will intensify as a result of this. A study using detailed data of Holocene Tagus River flooding combined with detailed climate models and water and sediment discharge models would provide valuable new insight in the response of a major fluvial system in this climatically sensitive region.

## SUMMARY

Changing global climate as a result of strong human impact on system earth, is receiving much scientific, political and public attention. For a thorough understanding of the effects of global climatic changes, a look at the geological past provides valuable insights. Geological records in sediments of coastal zones bear traces of both terrestrial and marine processes. Coasts with a narrow continental shelf (up to 200 m water depth) and a steep continental slope enable robust geological reconstructions because of the high sediment accumulation rates and well-defined sediment pathways. At *passive continental margins*, thick sediment layers with high resolution geological archives are present due to a large fluvial sediment supply. Furthermore, disturbances by volcanoes and large earthquakes are absent, making passive continental margins well suited to improve the fundamental understanding of sedimentary processes on continental margins.

Most studies of continental margins either focus on the terrestrial part or on the marine part of the system. To improve the understanding of sedimentary processes and to unravel the controls on terrestrial and marine sedimentation, an integrated palaeoenvironmental reconstruction of a passive margin including the delta, coast, continental shelf and slope, and the deep sea abyssal plain is needed. Special emphasis should be given to the significant influence of transport and sedimentation processes under varying climates. For this purpose the collaborative research project SEDPORT was initiated within the European Science Foundation (ESF) EUROCORES EUROMARGINS framework. The general aims of this project are:

1. To better determine the influence of terrestrial and marine sediment transport mechanisms on the composition and physical properties of the last glacial to Holocene margin sediment cover with respect to modern environmental conditions;
2. To investigate how sedimentation processes have changed under varying climate conditions affecting ocean circulation, sea level, continental weathering, vegetation and precipitation since the last glacial into the Holocene.

The Iberian passive margin near the Lower Tagus Valley is well suited for such a study. Due to the narrow exit of the valley southwest of Lisbon, the Tagus River acts as a point source of sediment. The narrow and deep bedrock-confined Lower Tagus Valley is an efficient trap for fluvial, tidal and marine deposits and enables robust sediment pathway and volumetric reconstructions. During sea-level lowstand the narrow continental shelf caused efficient sediment bypassing to the Tagus Abyssal Plain while during highstand sea

level, sediments were efficiently trapped in the Lower Tagus Valley and on the narrow shelf.

The general aims of this study are elaborated through a series of specific aims, which resulted in two intermingled lines of research which have the correlation of land and sea records as a common background:

1. Reconstructing the *palaeogeographic evolution and fluvial-marine sediment budget of the Tagus depositional system* using facies, sedimentary architecture, sequence-stratigraphy and timing of sediment deposition;
2. Identifying the *controls* on the nature and architecture of incised-valley successions, changing sediment fluxes and fluvial-marine depocenter migrations.

To achieve these aims, a large dataset was created for the Tagus depositional system, consisting of hand and mechanical cores from the Lower Tagus Valley floodplain and three marine cores; two from the continental shelf (D13882 and GeoB-8903-1) and one from the Tagus Abyssal Plain (MD03-2698). Samples from these cores were used for multi-proxy measurements (radiocarbon age, grainsize, and heavy mineral, organic matter, carbonate, floral, and faunal content). Additionally, lithological and sedimentological information from 284 cone penetration tests, and continuous and discontinuous geological cores used for geotechnical studies was used. Geological cross sections and palaeogeographic maps were constructed to facilitate the calculation of sediment budgets.

### **The palaeogeographic evolution and fluvial-marine sediment budget of the Tagus depositional system**

#### *Around 20,000 years ago | lowstand sea level: incision*

Lowstand sea level (120 m lower than at present) and a direct connection between the Lower Tagus Valley and the ocean across the narrow (~30 km) continental shelf caused incision of a deep valley (~70 m near Lisbon) by the Tagus River which reached up to ~100 km inland. Fluvial sediments were efficiently bypassing the largely exposed shelf via incised valleys directly funnelling into the heads of marine canyons and to the deep sea (4000-5000 m depth; Tagus Abyssal Plain), where the main depocentre was located. Bypassing of fluvial sediment resulted in high-frequency turbidite deposition on the Tagus Abyssal Plain between 20,000 and 15,000 years ago. The Tagus was a braided, and since ~14,000 years ago a single-channel river. The deep incision of the valley prevented large-scale erosion by a transgressive marine system. Consequently a thick *lowstand systems tract* has been preserved. The deep incision of the Lower Tagus Valley and the efficient sediment bypass, show that besides catchment

size and sea level, the width of the shelf is an important downstream control on incision dimension by means of fluvial gradient and landward extent of regressive erosion.

#### *20,000-12,000 years ago | rapid relative sea-level rise: transgression*

Since ~20,000 years ago relative sea level rose rapidly and at ~12,000 years ago, the rising sea level pushed the Tagus fluvial system far inland, creating accommodation space and ultimately drowning the Lower Tagus Valley. On the Tagus Abyssal Plain rapid sedimentation continued until ~11,500 years ago because of a continued supply of fluvially derived sediment. The final stage of rapid deep-sea deposition coincides with the onset of increased sedimentation on the shelf at ~13,500 years ago, which continued until ~10,500 years ago and reflects a landward depocentre shift caused by relative sea-level rise.

217

#### *12,000-7000 years ago | final stage of relative sea-level rise: transgression*

The final stage of relative sea-level rise from ~40 m below present-day sea level at ~12,000 years ago to present-day sea level at ~7000 years ago resulted in transgression in the deeply incised lowstand valley (*transgressive systems tract*). Because of this transgression, the accommodation space was maximal in the Lower Tagus Valley and the depocentre shifted landward. The morphology of the valley with its narrow exit created a sheltered inland basin upstream of Lisbon, strongly reducing the effect of storms and storm surges in the drowned valley. Since ~7000 years ago the Lower Tagus Valley was completely drowned and occupied by tidal and marine environments which reached up to 100 km inland. The valley trapped increasing sediment volumes, which limited export to the shelf. Therefore, sedimentation on the shelf strongly decreased during the early stage of the Holocene (~10,500-5000 years ago).

#### *7000-2000 years ago | fluvial sediment supply: regression*

A stable relative sea level since ~7000 years ago resulted in regression marked by bayhead delta progradation and the build-up of a fluvial wedge in the Lower Tagus Valley (*highstand systems tract*). Around 5000 years ago, the valley was filled to such an extent that gradually sediment export occurred again, and on the shelf a subaqueous delta and mudbelt built up, reflecting a seaward depocentre shift. After ~7000 years ago a continued fluvial sediment supply combined with the protected setting of the valley resulted in mainly upstream controlled regression. The fluvial sediment wedge prograded downstream and simultaneously the Holocene onlap point migrated upstream. Between ~5500-1000 years ago the flooding history of the Lower Tagus Valley was dominantly controlled by climatic variability.

### *2000-0 years ago | human impact: increased fluvial-marine sedimentation*

Since ~2000 years ago the Tagus fluvial-marine depositional system increasingly reflects land-use changes in the catchment. In the floodplain grainsize coarsened and sedimentation rate increased. This is explained by an increased flooding frequency and/or intensity. On the Tagus shelf the mudbelt grain-size fined, together with a higher sedimentation rate. The fining grainsize is a consequence of a strongly increased suspended sediment flux towards the shelf. The higher concentration of fine mud may have resulted in subdued winnowing and therefore a better preservation of fine-grained sediment. The observed changes are interpreted as the result of increased erosion of catchment slopes due to deforestation and increasing agriculture. Four depositional phases related with human impact on the natural landscape in the Tagus catchment were identified (~2300/~1600/~1100/~670 years ago), the latter two being strongest.

### *Sediment budgets at a passive continental margin*

Using a (semi-) quantitative approach to quantify sediment fluxes and budgets of the fluvial-marine depositional system, an up to 2.5 times higher flux and storage of sediment during the last ~7000 years was identified. This increased flux was favoured by more arid climate conditions and land-use changes. The analysis of the fluvial flooding history using local observations (cores) did not identify the increased flux. This illustrates the advantage of a (semi-) quantitative approach using sediment budgets, because it provides a time-integrated three-dimensional reconstruction of sediment supply and deposition. It underlines the importance of an integrated land-ocean study and the quantification of fluvial-marine sediment fluxes to identify effects of climate change and human impact on depositional systems.

## **Controls**

The multi-disciplinary and multi-proxy approach utilized in the present study has clearly demonstrated the shelf region—situated at the confluence of terrestrial and marine processes—to be extremely sensitive to developments in the terrestrial and marine realms. The main controls responsible for sedimentary changes on the studied passive continental margin are:

- **Sea-level change:** this has a strong control on shifting sediment depocentres. Depocentre movement and sea-level change play a large role in the situation of large sediment bodies such as fluvial channels and turbidites, which are potential hydrocarbon reservoirs.
- **Configuration of the continental shelf:** the configuration of the continental shelf (narrow, incised by a river valley) greatly affects sediment transport and bypass to the deep sea, thereby affecting depocentre

location. A deeply incised inland river valley captures large sediment quantities during sea-level highstand, thereby limiting marine deposition. On the other hand, a deeply incised valley funnelling into the head of a submarine canyon efficiently bypasses sediment to the deep sea during sea-level lowstand.

- **Human impact:** using detailed sedimentological, chronological and historical data from the river valley, catchment and shelf, the effect of human impact in the river catchment could be traced from source-to-sink. Extensive human impact thereby sheds light on the direction, scale and timing of the response of the fluvial-marine depositional system to large-scale external forcing.
- *Tectonic activity:* despite historic tectonic activity (large earthquakes in 1531, 1755 and 1909 AD) the horizontal relative sea-level curve since ~7000 years ago suggests that neotectonic uplift or subsidence were limited. Further, the present study has not identified sedimentological features in the fluvial-marine depositional system which could be clearly linked with earthquakes or tsunamis. The relatively thin lowstand braided Tagus River deposits directly overly Tertiary deposits, implying that subsidence in the Lower Tagus Valley was absent during the Quaternary period. Long-term tectonic uplift prevailed, preventing the deposits from being lowered below the scour depth of younger fluvial systems.
- *Fluvial sediment supply and climate change:* a stable sea level during the last 7000 years resulted in the increased relative importance of fluvial sediment supply, which controlled regression and fluvial progradation. Quantitative estimates of sediment volume for the last ~12,000 years show a drastically increased sediment flux and storage in the Tagus fluvial-marine depositional system after ~7000 years ago, which was favoured by climate change. Since the end of the African Humid Period (~5,500 years ago) regional climate resulted in more arid conditions and regional forest-cover decreased. Land-use changes since ~2000 years ago were added to that causing an increased vulnerability to soil erosion which resulted in an up to a 2.5 times higher sediment flux to the Lower Tagus Valley and shelf. The increased sediment flux did not coincide with a gradual increase in (peak) flood discharges during the last ~6000 years, although three phases of increased fluvial activity were established in distal floodbasin settings (6500-5500, 4900-3500 and 1000-0 years ago). Quantitative estimates of sediment volume deposited by the Tagus depositional system have enabled calculation of the total mechanical denudation rate for the Tagus catchment, which equals ~0.09 mm/y. This value is in agreement with long-term (10-40 ka) erosion rates from Central European catchments.

## RESUMO

As alterações climáticas como resultado do forte impacto humano na Terra, tem recebido uma importante atenção por parte da comunidade científica bem como do poder político e da população em geral. Para um conhecimento detalhado dos efeitos das alterações climáticas globais, é necessário um olhar sobre o registo geológico, pois fornece um entendimento valioso. Os registos geológicos nos sedimentos das zonas costeiras contêm marcas de processos terrestres e marinhos.

As zonas costeiras com uma plataforma continental estreita (até 200 m de profundidade) e com uma encosta íngreme permitem reconstruções geológicas robustas, devido às elevadas taxas de acumulação de sedimentos e vias de transporte de sedimentação bem definidos. Nas *margens passivas continentais*, as camadas espessas com registos geológicos de alta resolução existem devido ao elevado fornecimento de sedimentos fluviais. Adicionalmente, devido a ausência de perturbações por parte de vulcões ou de sismos de grande intensidade, as margens passivas continentais são adequadas para uma melhoria no entendimento fundamental dos processos sedimentares nas margens continentais.

A maior parte dos estudos das margens continentais incide ou na componente terrestre ou na componente marinha do sistema. De modo a melhorar o entendimento dos processos sedimentares e para desvendar quais os controlos da sedimentação terrestre e marinha, é necessária uma reconstrução paleoambiental integrada de uma margem passiva que inclua a parte deltaica, costeira, plataforma e talude continentais, e planície abissal profunda. Uma ênfase especial deve ser dada aos processos de transporte e sedimentação sujeitos a climas variados desde a zona mais distante da costa até ao oceano. Por esta razão, iniciou-se dentro da estrutura da European Science Foundation (ESF) EUROCORES EUROMARGINS o projecto de investigação conjunta SEDPORT. Os objectivos gerais do projecto são:

1. Melhorar a compreensão dos mecanismos de transporte terrestre e marinho na composição e propriedades físicas da cobertura sedimentar que vai da última glaciação até ao Holocénico (de há 20.000 anos até à actualidade), com atenção às condições ambientais actuais em geral;
2. Averiguar como os processos de sedimentação mudaram quando sujeitos a condições climáticas diversas que tiveram influência na circulação oceânica, no nível do mar, na meteorização continental, na vegetação e precipitação desde a última era glacial até ao Holocénico.

Para este estudo, a margem passiva Ibérica junto ao Vale Inferior do Tejo é adequada. Devido à saída estreita do vale a sudoeste de Lisboa, o Rio Tejo actua

como fonte de sedimentos. O Vale Inferior do Tejo que é estreito e confinado por um soco rochoso profundo, é uma armadilha eficiente para depósitos, fluviais, tidais e marinhos e permite uma reconstrução robusta dos percursos e volumes sedimentares. Durante um nível do mar baixo devido à estreita plataforma continental, os sedimentos atravessam/passam de um forma eficiente para a Planície Abissal do Tejo (5000 m de profundidade), no entanto, durante um nível do mar alto os sedimentos ficam retidos no Vale Inferior do Tejo ou na estreita plataforma.

Os objectivos gerais deste estudo foram elaborados através de uma série de objectivos mais específicos, que resultou em duas linhas de investigação interligadas, que têm como fundo comum a correlação entre os registos terrestres e marinhos:

1. Reconstruir a *evolução paleogeográfica e a provisão sedimentar marinho-fluvial no sistema deposicional do Tejo*, utilizando fáceis, arquitectura sedimentar, sequência-estratigráfica e período de deposição sedimentar;
2. Identificar os *controles* na natureza e arquitectura das sucessões de vales encaixados modificando os fluxos sedimentares e as migrações dos depocentros marinho-fluviais.

Para atingir estes objectivos, foi compilado um grande volume de dados para o sistema deposicional do Tejo, com sondagens manuais e mecânicas na planície de inundação do Vale Inferior do Tejo e três sondagens de pistão, dois na plataforma continental (D13882 e GeoB-8903-1) e um da Planície Abissal do Tejo (MD03-2698). Amostras destes testemunhos de sondagens foram utilizados para medições de multi-indicadores (datações radiocarbono, granulometria, minerais pesados, matéria orgânica, carbonatos, flora e fauna). Adicionalmente, foram utilizados dados geotécnicos com a informação litológica e sedimentológica de 284 testes de penetração e testemunhos de sondagem geológicos contínuos e descontínuos. De modo a facilitar o cálculo do balanço sedimentológico foram elaborados perfis geológicos e mapas paleogeográficos.

## **A evolução paleogeográfica e a provisão sedimentológica fluvial-marinha no sistema deposicional do Tejo**

*Aproximadamente 20.000 anos atrás | nível do mar baixo: encaixamento*

O nível do mar baixo (120 m abaixo do actual) e a ligação directa entre o Vale Inferior do Tejo e o oceano através da estreita (~30 km) plataforma continental o Rio Tejo causou o encaixe de um vale profundo (~70 m junto a Lisboa) que se estendeu até 100 km para o interior. Os sedimentos fluviais foram eficientemente transportados passando a plataforma exposta por vales submarinos

e canalizando estes sedimentos directamente para as cabeceiras dos canhões submarinos e em direcção à planície abissal (4000-5000 m de profundidade, Planície Abissal do Tejo), onde estava localizado o principal depocentro. Este transporte de sedimentos fluviais resultou numa deposição turbidítica de alta-frequência na Planície Abissal do Tejo a 20.000 e 15.000 anos atrás. O Tejo caracterizava-se pelas várias ramificações e há cerca de ~14.000 anos passou a ser um rio de canal único. Os vales profundos encaixados impediram uma erosão a larga escala por um sistema transgressivo marinho. Consequentemente ficou registada uma camada espessa do período de mar baixo (*lowstand systems tract*). O forte encaixe do Vale Inferior do Tejo e o transporte eficiente dos sedimentos, mostra que apesar do tamanho da captura e o nível do mar, a largura da plataforma é um importante controlo a jusante da largura do encaixe, na inclinação fluvial e na extensão para o interior da erosão regressiva.

#### *20.000 a 12.000 anos atrás | aumento súbito do nível do mar: inundação do vale*

Por volta de há 20.000 anos atrás houve uma subida rápida do nível do mar, e à aproximadamente 12.000 anos o mar empurrou o sistema fluvial do Tejo para o interior, criando um espaço de acomodação e por fim submergido o Vale Inferior do Tejo. Na Planície Abissal a sedimentação efectuou-se a um ritmo acelerado até ~11.500 anos atrás devido a um fornecimento constante de sedimentos fluviais. A etapa final da deposição em oceano profundo coincide com a crescente sedimentação na plataforma, por volta de 13.500 anos atrás, processo que continuou até ~10.500 anos atrás e reflecte a migração do depocentro para o interior por influência de um aumento relativo do nível do mar.

#### *12.000 a 7000 anos atrás | etapa final da subida relativa do nível do mar: submersão completa do vale*

A etapa final da subida relativa do nível do mar de ~40 m abaixo do actual nível do mar à cerca de 12.000 anos atrás, até ao nível do mar actual há ~7000 anos, resultou numa transgressão do vale profundo (*transgressive systems tract*). Devido a esta transgressão, o espaço de acomodação foi máximo no Vale Inferior do Tejo e o depocentro migrou para terra. A morfologia do vale com uma saída estreita criou uma bacia terrestre abrigada a montante de Lisboa, que reduziu grandemente o efeito de tempestades no vale submerso. Desde há ~7000 anos atrás o Vale Inferior do Tejo foi completamente submerso e foi ocupado até 100 km para o interior por ambientes tidais e marinhos. O vale encurralado aumentou o volume de sedimentação, o que limitou a carga sedimentar para a plataforma. Deste modo, a sedimentação na plataforma diminuiu grandemente no início do Holocénico (~10.500-5000 anos atrás).

### *7000 a 2000 anos atrás | fornecimento fluvial de sedimentos: estabelecimento do delta*

Um nível do mar estável há ~7000 anos atrás resultou numa regressão marcada por uma progradação deltaica e a constituição de uma cunha fluvial no Vale Inferior do Tejo (*highstand systems tract*). Há 5000 anos atrás, o vale foi preenchido numa extensão tal que teve que ocorrer um reinício do transporte de sedimentos, e na plataforma formaram-se um delta subaquático e uma faixa lodosa, reflectindo uma migração do depocentro em direcção ao mar. Depois, há ~7000 anos atrás um fornecimento contínuo de sedimentos combinado com a localização protegida do vale resultou numa regressão controlada a montante. A cunha de sedimentos fluviais progradou para jusante e simultaneamente o ponto *onlap* do Holocénico migrou a montante. Por volta de ~5500-1000 anos atrás a história de inundações do Vale Inferior do Tejo foi predominantemente controlada por alterações climáticas.

### *2000 a 0 anos atrás | impacto humano: um aumento de sedimentação fluvio-marinha*

Há 2000 anos atrás há um reflexo na mudança de utilização da terra na captura, no sistema fluvio-marinho deposicional do Tejo. Na planície de inundações a granulometria da sedimentação tornou-se mais grosseira. Na plataforma do Tejo a granulometria da faixa lodosa tornou-se mais fina, juntamente com um aumento da taxa de sedimentação. A diminuição da granulometria é uma consequência do aumento do fluxo de sedimentos que chega à plataforma. A alta concentração de argila fina poderá ter resultado numa melhor preservação dos sedimentos de granulometria fina (*subdued winnowing*). Estas mudanças podem ser explicadas pelo aumento da erosão dos declives de captura devido à desflorestação e aumento da actividade agrícola, o que resultou num aumento intensidade e/ou frequência de cheias. Foram identificadas quatro fases de deposição relacionadas com o impacto antropogénico na paisagem natural da captura do Tejo (~2300/~1600/~1100/~670 anos atrás), sendo as duas últimas foram as mais intensas.

### *O balanço sedimentar numa margem passiva continental*

Utilizando uma abordagem (semi-) quantitativa para quantificar os fluxos e provisões de sedimentação num sistema deposicional fluvio-marinho, foi identificado um fluxo e armazenamento sedimentar 2,5 vezes superior nos últimos ~7000 anos. Este aumento do fluxo foi favorecido por condições de clima mais árido e uma mudança da utilização da terra. Da análise da história de inundações fluviais utilizando observações locais (testemunhos de sondagem) não foram identificados aumentos de fluxo. Isto ilustra a vantagem de uma abordagem (semi-) quantitativa utilizando balanços sedimentares, porque

proporciona reconstrução da produção e deposição sedimentar tridimensional e integrada no tempo. Sublinha a importância de um estudo integrado terra-oceano e da quantificação dos fluxos sedimentares fluvio-marinhos para identificar os efeitos das mudanças climáticas e o impacto do homem nos sistemas deposicionais.

## Controlos

A abordagem multi-disciplinar e recorrendo a multi-indicadores utilizada no presente estudo mostrou claramente que a região da plataforma, situada na confluência dos processos marinhos e terrestres, é extremamente sensível a desenvolvimentos nos domínios terrestre e marinho. Os principais controlos responsáveis pelas alterações sedimentares na margem passiva estudada são:

- Variação do nível do mar: esta variação tem um forte controlo no deslocamento dos depocentros sedimentares. O movimento dos depocentros e a variação do nível do mar desempenham um papel importante em grandes corpos sedimentares como canais fluviais e turbiditos, que poderão ser potenciais reservatórios de hidrocarbonetos.
- Configuração da plataforma continental: a configuração da plataforma continental (estreita, encaixada por um vale de rio) afecta grandemente o transporte sedimentar para o grandes profundidades, afectando deste modo a localização de depocentros. Um vale fluvial encaixado captura grandes quantidades de sedimentos durante períodos de nível do mar alto, limitando assim a deposição marinha. Por outro lado, durante períodos de nível do mar baixo um vale submarino profundo canaliza para a cabeceira de um canhão submarino e transporta eficazmente os sedimentos para mar profundo.
- Impacto humano: utilizando dados sedimentológicos, cronológicos e históricos detalhados do vale do rio, na captura e na plataforma, o efeito do impacto humano na captura do rio, pode ser seguida desde a origem até a profundidade (planícies abissais). Desta forma, o impacto humano extensivo demonstra a direcção, escala e tempo de resposta de uma força externa no sistema deposicional fluvio-marinho a uma escala alargada.
- Actividade tectónica: Apesar da actividade tectónica histórica (sismos de grande intensidade em 1531, 1755 e 1909) a curva de forma horizontal relativa aos últimos ~7000 anos sugere que o levantamento neotectónico ou subsidência são incipientes. Além disso, o estudo não identificou características sedimentológicas no sistema deposicional marinho-fluvial que possam ser claramente relacionados com sismos ou tsunamis. Os depósitos relativamente fino e ramificado do Rio Tejo situado directamente sobre o Terciário, implicam que durante o período Quaternário (últimos 2,5 milhões de anos) a subsidência no Vale Inferior do Tejo não existiu. Preva-

leceu durante um período longo, um levantamento tectónico impedindo que os depósitos baixassem a um nível inferior relativamente à profundidade do encaixe dos sistemas fluviais recentes.

- Fornecimento fluvial de sedimentos e alterações climáticas: um nível do mar estável durante os últimos 7000 anos resultou no aumento da importância relativa do fornecimento de sedimentos fluviais, que controlou a regressão e a progradação fluvial. Estimativas quantitativas do volume de sedimentos dos últimos ~12000 anos demonstraram um fluxo sedimentar crescente e a deposição no sistema fluvio-marinho do Tejo a aproximadamente 7000 anos atrás, que foi favorecida pelas alterações climáticas. Desde o fim do Período Húmido Africano (aproximadamente 5500 anos atrás) as condições climáticas regionais tornaram-se mais áridas. A diminuição da cobertura florestal e a mudança da utilização do solo contribuiu para um aumento da vulnerabilidade do solo à erosão, que resultou num fluxo de sedimentação no Vale Inferior do Tejo e na plataforma 2,5 vezes superior. Este aumento de fluxo de sedimentação não coincidiu com um aumento gradual das inundações durante os últimos ~6000 anos, apesar de três fases de aumento de actividade fluvial se terem fixado numa bacia de inundação mais distal (6500-5500, 4900-3500 e 1000-0 anos atrás). Estimativas quantitativas sobre volume de sedimentos depositados no sistema deposicional do Tejo, permitiram o cálculo da taxa total de denudação mecânica para a captura do Tejo, cujo total é de cerca de 0,09 mm/ano. Verifica-se que este valor está concordante com as taxas de erosão a longo prazo (10.000-40.000 anos) para as capturas na Europa Central.

## SAMENVATTING

226

De huidige klimaatverandering heeft grote gevolgen voor de aarde en krijgt daarom veel wetenschappelijke, politieke en maatschappelijke aandacht. Door veranderende weersystemen wordt het op sommige plaatsen droger en op andere plaatsen natter. Ook zullen extreme weersgebeurtenissen, zoals langdurige droogtes en hevige regenbuien, vaker voorkomen. Daarbovenop komt nog de zeespiegelstijging, veroorzaakt door het opwarmen en uitzetten van zeewater en door het smelten van landijs. Vooral in laaggelegen kustgebieden neemt de kans op overstromingen toe en juist daar woont het grootste gedeelte van de wereldbevolking.

Om de gevoeligheid voor klimaatverandering beter te begrijpen, kijkt deze studie naar de geologische geschiedenis van kustgebieden. Het samenspel tussen land- en zeeprocessen leidt tot het afwisselend afzetten en eroderen van grote hoeveelheden zand en klei. Deze processen bepalen of de zee terrein wint ten opzichte van het land of andersom en ze worden sterk beïnvloed door klimaatverandering. Grote rivierdelta's zoals die van de Mississippi en lange estuaria zoals die van de Westerschelde zijn bijvoorbeeld ontstaan door verschillende combinaties van aanvoer van zand en klei, getijde en zeespiegelstand.

Door de ontstaansgeschiedenis van bestaande kustgebieden te reconstrueren, kan worden onderzocht hoe het transport en de afzetting van sedimenten zijn beïnvloed door klimaatveranderingen in het verleden. Met deze kennis kunnen we beter voorspellen wat de gevolgen van de huidige klimaatverandering zullen zijn; *the past is the key to the present*. De routes waarlangs de sedimenten (zand en klei) ooit zijn getransporteerd, zijn vaak nog goed te herkennen, vooral in kustgebieden waar het continentaal plat (waterdieptes tot 200 m, vergelijkbaar met de Noordzee) slechts enkele tientallen kilometers breed is en de helling naar de diepzee steil is. Rivieren die hier in zee uitkomen, voeren grote hoeveelheden sediment aan, wat in dikke lagen wordt afgezet op de zeebodem. Wanneer kustgebieden niet worden verstoord door vulkanen en grote aardbevingen (zogenaamde *passieve continentranden*), kan rustige afzetting plaatsvinden van het door de rivieren aangevoerde sediment. Dit maakt het makkelijker om transport en afzetting van sediment te bestuderen om zo de reactie van sedimentaire processen op klimaatveranderingen in het verleden beter te begrijpen.

De meeste studies van continentranden beperken zich tot het landgedeelte of het zeegedeelte, terwijl dit onderzoek juist naar de continentrand als *geheel* kijkt. Om alle processen die sturend zijn voor land- en zeesedimentatie te ontrafelen, is het nodig om zowel de rivierdelta, de kust, het continentaal plat, de helling naar de diepzee als de diepzee zelf (ca. 5000 m waterdiepte) te bestuderen. Om het onderzoek naar de effecten van klimaatverander-

ing op sedimenttransport en sedimentatie grootschalig aan te pakken is het Europese onderzoeksproject SEDPORT opgezet binnen het EUROCORES EUROMARGINS programma van de European Science Foundation (ESF). De algemene doelstellingen van dit project zijn om voor de periode sinds het maximum van de laatste ijstijd (ca. 20.000 jaar geleden):

1. Beter inzicht te krijgen in het samenspel tussen rivier- en zeeprocessen wat bepaalt waar wanneer welke sedimenten langs de continentrand afgezet worden;
2. Te bepalen hoe deze processen worden beïnvloed door veranderingen op het land (neerslag, vegetatie, erosie) en in zee (zeespiegelstand, stromingen) die het gevolg zijn van de klimaatverandering.

227

De passieve continentrand aan de westkant van het Iberische Schiereiland nabij Lissabon (Portugal) is zeer geschikt voor een dergelijke studie. De Taag heeft een groot achterland (met 1008 km lengte is het de twaalfde rivier van Europa) en stroomt van het warme en droge binnenland van Spanje naar de koelere nattere Atlantische kust van Portugal. Hierdoor levert de rivier veel sediment en is het riviersysteem gevoelig voor klimaatveranderingen. Door de smalle verbinding van het Beneden Taagdal met de oceaan is de Taag een puntbron van sediment; dat is behulpzaam voor de reconstructie van sedimenttransportroutes. Het smalle en diep ingesneden Beneden Taagdal wordt omgeven door ouder gesteente waardoor het een zeldzame beschutte ligging heeft. Hierdoor hebben duizenden jaren lang rivier-, getijde- en zeersedimenten het dal in alle rust kunnen opvullen. Het Taagdal is hierdoor een prachtig geologisch archief aan de hand waarvan sedimenttransportroutes en -volumes kunnen worden gereconstrueerd.

De algemene doelstellingen van het SEDPORT project zijn vertaald naar een aantal specifiekere doelstellingen voor het bestuderen van het Beneden Taagdal in deze studie. Deze specifiekere doelstellingen kunnen worden ondergebracht in de volgende twee verweven onderzoekslijnen, die de correlatie van land- en zeersedimenten als gemeenschappelijk doel hebben:

1. Het uitzoeken van *wat er met de Taag is gebeurd* gedurende de laatste 20.000 jaar, daarbij lettend op waar en wanneer op land en in zee wat voor sedimenten werden afgezet en hoeveel dat was;
2. Het bepalen wat de *oorzaken* waren van de waargenomen veranderingen.

Om deze doelen te bereiken is een grote hoeveelheid gegevens verzameld in het sedimentatiesysteem van de Taag. Deze gegevens bestonden uit hand- en mechanische boringen in het Beneden Taagdal, en uit zeeboringen. Twee zeeboringen zijn gedaan op de bodem van het continentaal plat en één op

de bodem van de diepzee. De monsters die uit de land- en zeeboringen zijn genomen, werden gebruikt voor het bepalen van ouderdom, korrelgrootte, zware mineralen samenstelling, organisch materiaal- en kalkgehalte, en plant- en dierfossielen. Daarnaast werd informatie uit 284 sonderingen en geologische boringen uit geotechnische studies gebruikt. Aan de hand van al deze gegevens werden dwarsdoorsneden en kaarten gemaakt, waarmee vervolgens het transport en de sedimentatie van zand en klei konden worden gereconstrueerd. De volumes sediment die in de loop der tijd door de Taag zijn afgezet, zijn berekend met behulp van 3D computersoftware. Deze volumes zijn ook vergeleken met de hoeveelheden sediment die door de eeuwen heen uit het achterland verdwenen zijn in een zogenaamd *sediment budget*.

### **Wat is er met de Taag gebeurd tijdens de laatste 20.000 jaar?**

#### *Circa 20.000 jaar geleden | lage zeespiegelstand: dalvorming*

Ongeveer 20.000 jaar geleden stond de zeespiegel 120 meter lager dan tegenwoordig en bestond er een directe verbinding tussen het Beneden Taagdalen en de oceaan via een diep dal in het ~30 km smalle continentaal plat. Hierdoor werd het Beneden Taagdalen tot 70 m diep en 100 km landinwaarts ingesneden. Bijna al het riviersediment werd efficiënt afgevoerd naar de bodem van de diepzee via rivierdalen en onderzeese canyons. De doorvoer van sediment naar de diepzee resulteerde in veel troebelheidsstromen (onderzeese aardverschuivingen) die tussen 20.000 en 15.000 jaar geleden veel van het sedimenttransport naar de diepzee voor hun rekening namen.

Tot 14.000 jaar geleden was de Taag een vlechtende rivier met veel zandbanken. Daarna concentreerde het water zich onder invloed van klimaat- en vegetatieverandering in één geul. Het Beneden Taagdalen was diep en steil. Toen de zeespiegel begon te stijgen, liep het dal zo snel onder water dat de oudere rivierafzettingen werden bedekt met zeeklei en heel goed bewaard bleven. Door de combinatie van de lage zeespiegel tijdens de ijstijd en het smalle continentale plat, is de Taag één van de diepst en verst landinwaarts ingesneden rivierdalen langs de Europese kust.

#### *20.000-12.000 jaar geleden | snelle zeespiegelstijging: eerste overstroming*

Vanaf 20.000 jaar geleden steeg de zeespiegel snel (ca. 1 meter per eeuw) en rond 12.000 jaar geleden had de stijgende zeespiegel een deel van het Beneden Taagdalen verdrongen en de rivier landinwaarts geduwd. In het ondergelopen Beneden Taagdalen ontstond steeds meer ruimte om sediment in te vangen. Doordat steeds meer sediment in het Beneden Taagdalen werd afgezet, nam het sedimenttransport naar de diepzee geleidelijk af. De laatste periode van snelle sedimentatie in de diepzee valt dan ook samen met het begin van de sedimentatie op het continentaal plat rond 13.500 jaar geleden. De snelle sedimentatie

op het continentaal plat eindigde ongeveer 10.500 jaar geleden. Deze veranderingen weerspiegelen een landwaartse verplaatsing van het zwaartepunt van sedimentatie als gevolg van zeespiegelstijging.

### *12.000-7000 jaar geleden | het laatste stadium van zeespiegelstijging: verdrinking*

Van 12.000-7000 jaar geleden steeg de zeespiegel nog 40 meter tot aan het huidige niveau. Gedurende dit laatste stadium van zeespiegelstijging verdronk het Beneden Taagdal helemaal. De vorm van het dal met zijn smalle uitgang, zorgde voor een beschutte baai ten oosten van het huidige Lissabon waarin golven en golfwerking beperkt waren. In het begin stond het Beneden Taagdal geheel onder water tot wel 100 km landinwaarts. Getijdenstroming en golfwerking domineerden de sedimentatie- en erosieprocessen. Het verdrongen dal ving steeds meer sediment in, waardoor er steeds minder sediment naar zee werd afgevoerd. De zeespiegelstijging zorgde voor een verdere landwaartse verschuiving van het zwaartepunt van sedimentatie.

### *7000-2000 jaar geleden | fluviatiele sedimentaanvoer: deltavorming*

Een min of meer stabiele zeespiegel tijdens de afgelopen ca. 7000 jaar en een constante aanvoer van sediment door de Taag zorgden voor de vorming van een delta. De delta bouwde zich stroomafwaarts uit en vormde een steeds dikker wordende laag riviersediment in het Beneden Taagdal. Rond 5000 jaar geleden was het Beneden Taagdal al zo ver opgevuld met sediment, dat er langzaam weer sediment werd doorgevoerd naar zee. Hierdoor ontstonden op het continentaal plat een onderwaterdelta en slibafzettingen. Dit omslagmoment weerspiegelt een zeewaartse verplaatsing van het zwaartepunt van sedimentatie. Door de beschermde ligging van het dal werd de uitbouw van de delta niet tegengewerkt door zeestromingen en golferosie. De delta bleef zich stroomafwaarts uitbouwen en tegelijkertijd werden bovenstroomse gebieden ook langzaam gevuld met sediment. In de opbouw van de sedimentlagen zijn de gevolgen van klimaat- en vegetatieveranderingen in het stroomgebied goed herkenbaar.

### *2000 jaar geleden tot nu | menselijke invloed: toegenomen land- en zeesedimentatie*

Gedurende de laatste ca. 2000 jaar werd sedimentatie in het land-zee bereik van het Taag-systeem in toenemende mate beïnvloed door veranderend landgebruik in het stroomgebied. Vooral tijdens de Middeleeuwen begon grootschalige ontbossing, wat zorgde voor grote hoeveelheden sediment die via de rivieren naar de delta en de zee werden getransporteerd. In de delta nam de korrelgrootte en sedimentatiesnelheid van het overstromingssediment

toe. Op het continentaal plat werden de slibafzettingen echter fijner, terwijl ook hier de sedimentatiesnelheid toenam. De verfijning van de korrelgrootte is het gevolg van een sterk toegenomen aanvoer van fijn sediment. De oceaanstromingen waren niet sterk genoeg om deze grote hoeveelheid fijn sediment af te voeren, waardoor meer fijn sediment de zeebodem bereikte en bewaard bleef. De waargenomen veranderingen werden verklaard door toegenomen erosie vanaf hellingen in het stroomgebied. Dit werd veroorzaakt door ontbossing en toenemend landgebruik, waardoor overstromingen van de Taag vaker voorkwamen en intensiever waren.

Er zijn vier afzettingsfasen onderscheiden op land en in zee die zijn toegeschreven aan ontbossing en toenemend landgebruik in het stroomgebied van de Taag. Deze fasen vonden plaats rond ca. 2300, 1600, 1100 en 670 jaar geleden, waarbij de laatste twee fasen het sterkst waren.

#### *Sedimentbudget van een passieve continentrand*

Dit is een van de eerste studies die heeft berekend hoeveel sediment er in een sedimentatiesysteem zowel op land als in zee is afgezet. Door de volumes sediment die zijn afgezet in de periodes 12.000-7000 en 7000-0 jaar geleden met elkaar te vergelijken, blijkt dat tijdens de laatste 7000 jaar ongeveer twee en een half keer zoveel sediment is afgezet dan in de periode daarvoor. Deze toegenomen sedimentatie werd veroorzaakt door een grotere sedimentaanvoer als gevolg van drogere klimaatomstandigheden en ontbossing, waardoor meer erosie optrad. Het voordeel van een grootschalige land-zee aanpak is dat lokale variatie in sedimentatie in ruimte en tijd een kleine rol speelt. Bovendien wordt bij een land-zee aanpak ook het naar zee afgevoerde sediment in de volumebepaling meegenomen. Dit sediment wordt bij een puur op landgegevens gebaseerde studie buiten beschouwing gelaten.

### **Wat waren de oorzaken van de waargenomen veranderingen?**

Deze studie hanteert een aanpak met gebruikmaking en vergelijking van verschillende gegevensbronnen. Hierdoor kon duidelijk worden aangetoond dat het continentaal plat, gelegen op het raakvlak van land- en zeeprocessen, erg gevoelig is voor de gevolgen van klimaatverandering. De belangrijkste sturende factoren voor sedimentaire veranderingen van de passieve continentrand zijn:

- **Zeespiegelverandering:** dit heeft veel invloed op de ligging van het zwaartepunt van sedimentatie. De verplaatsing van dit zwaartepunt en de verandering van de zeespiegel spelen een grote rol in de ligging van grote sedimentlichamen zoals rivergeulen en afzettingen van onderzeese troebelheidsstromen, welke bijvoorbeeld potentiële olie- en gasreservoirs zijn.
- **De vorm van het continentaal plat:** verschillende vormen (smal, in-

gesneden door een rivier) hebben veel invloed op sedimenttransport en sedimentdoorvoer naar de diepzee, en mede daardoor ook op de ligging van het zwaartepunt van sedimentatie. Een diep en ver landinwaarts ingesneden rivierdal vangt veel sediment in tijdens een hoge zeespiegel, waardoor sedimentatie in zee wordt beperkt. Aan de andere kant zorgt een diep ingesneden dal dat is verbonden met een onderzeese canyon voor efficiënte afvoer van sediment naar de diepzee gedurende een lage zeespiegel.

- **Menselijke invloed:** door gebruik te maken van gedetailleerde sedimentologische, chronologische en historische gegevens van zowel het stroomgebied, het rivierdal als het continentaal plat is het gevolg van menselijk handelen in het stroomgebied gereconstrueerd. Grootschalige menselijke invloed zorgt als het ware voor een mega-experiment dat laat zien hoe het sedimenttransport reageert op een verstoring.
- **Tektonische activiteit:** ondanks het feit dat grote aardbevingen in het recente verleden hebben plaatsgevonden (1531, 1755 en 1909 AD), suggereert de vlakke curve van de zeespiegelreconstructie voor de laatste 7000 jaar dat tektonische opheffing of daling beperkt waren. Tijdens deze studie zijn dan ook geen sedimentologische kenmerken aangetroffen die duidelijk het gevolg zijn van aardbevingen of tsunamis. De relatief dunne riviersedimenten die zijn afgezet tijdens de lage zeespiegelstand, liggen direct op oudere (Tertiaire) afzettingen. Dit toont aan dat er geen daling van het Beneden Taagdalen heeft plaatsgevonden gedurende de laatste 2,5 miljoen jaar. Langdurige opheffing had de overhand, waardoor de oude riviersedimenten werden opgeruimd door erosie door jongere riviersystemen. Dit in tegenstelling tot het dalende Nederland, waar de op elkaar gestapelde rivierafzettingen van de laatste miljoenen jaren wel bewaard zijn gebleven.
- **Sedimentaanvoer en klimaatverandering:** door een stabiele zeespiegel gedurende de laatste 7000 jaar, was de invloed van sedimentaanvoer door de rivier op sedimentatie relatief groot en vormde zich een delta. Bepalingen van het sedimentvolume laten een drastisch toegenomen sedimentaanvoer zien in het land-zee afzettingssysteem gedurende de laatste 7000 jaar. Dit kwam doordat er in deze periode veel bossen verdwenen waardoor de bodem gevoeliger werd voor erosie. Het verdwijnen van de bossen was het gevolg van het steeds droger wordende klimaat op het Iberische Schiereiland. Gedurende de laatste 2000 jaar kwam de mens daar nog bij met een groot aandeel in de ontbossing. Door deze veranderingen werd tot wel twee en een half keer meer sediment naar het Beneden Taagdalen en het continentaal plat gevoerd.

### Pollen diagram from marine core MD03-2698 (-4602 m)

Only calibrated radiocarbon-date midpoints are given; see Chapter 6 and Appendix 4 for details. Note that pollen sum includes *Pinus* pollen.

## CURRICULUM VITAE

244

Geert-Jan Vis was born on September 9, 1979 in Reeuwijk (the Netherlands). He finished secondary school at the Coenecoop College in Waddinxveen in 1997, and in September of the same year he started studying Physical Geography at Utrecht University. He specialized in Quaternary geology and fluvial sedimentology. He wrote his M.Sc. thesis together with Thijs Nales about the palaeogeographic evolution of the Old Rhine channel belt, west of the city of Utrecht. He did an internship with Alessandro Fontana from the Università degli Studi di Padova, where he studied the quaternary geology of a spring river in northeast Italy, also together with Thijs Nales. After graduation in 2003, he worked as junior project manager prospective research with archaeological consultancy company BAAC B.V. in Deventer.

In January 2004 he started his Ph.D. research at the Department of Climate Change and Landscape Dynamics of the Faculty of Earth and Life Sciences at VU University Amsterdam. He conducted fieldwork in the Lower Tagus Valley in Portugal in 2004 - 2007. During his time at VU University he supervised many students during different fieldworks, excursions and B.Sc. and M.Sc. projects. He organized several discussion meetings on River Systems Research and was member of the Netherlands Centre for Geo-ecological Research (ICG) Ph.D. Committee with Femke Tonneijk and Gilles Erkens. Among the courses followed are oral presentation skills and scientific writing. He presented the results of this work at many international meetings. The Ph.D. thesis will eventually result in five publications in international peer-reviewed journals, of which two have already been published.

Since October 2008, he is employed at TNO *Geological Survey of the Netherlands*, where he works for the Advisory Board of the Ministry of Economic Affairs.

# Fluvial Archives Group Biennial meeting 2010 in Portugal

*September 6-10th 2010*

The meeting will be held in Vila Velha de Ródão, a small town located on the north bank of the Tagus River, close to the Portuguese / Spanish border.

Two days of oral presentations (6th & 7th September) will take place in Ródão followed by a 3-day field excursion (8-10th September) that will showcase the long-term drainage record of the Tagus River and includes several stops in the Lower Tagus Valley.

## COLOFON

This research was carried out at:

VU University Amsterdam  
Faculty of Earth and Life Sciences  
Department of Climate Change and Landscape Dynamics  
De Boelelaan 1085  
1081 HV Amsterdam  
The Netherlands

The investigations were supported by the Division for Earth and Life Sciences (ALW) with financial aid from the Netherlands Organization for Scientific Research (NWO), project 855.01.050.

This work has been made possible thanks to the partial support of 01-LEC-EMA44F SEDPORT Project by the European Science Foundation under the EUROCORES Programme EUROMARGINS, through contract Nr. ERAS-CT-2003-980409 of the European Commission, DG Research, FP6.

Printing of this thesis was generously supported financially by the contribution of TNO Built Environment and Geosciences and an anonymous sponsor.

This work is a contribution to IGCP Project 495 "Quaternary Land-Ocean Interactions: Driving Mechanisms and Coastal Responses", and to the Fluvial Archives Group (FLAG).

GEOLOGICAL CROSS SECTIONS OF THE LOWER TAGUS VALLEY (Chapters 2 & 3)

**LEGEND**

**Facies Units**

- FU-1A: fluvial terrace deposits
- FU-1B: high-gradient fluvial channels
- FU-2: aggrading fluvial overbank
- FU-3A: brackish water marshes and tidal flats
- FU-3B: intertidal and subtidal flats
- FU-4: shallow-marine prodelta
- FU-5A: distributary mouth tidal bars with shells
- FU-5B: fluvially influenced tidal channels without shells
- FU-6A: condensed fluvial floodbasins
- FU-6B: fluvial floodbasins
- FU-7: natural levees and crevasses
- FU-8: fluvial channels
- peat-dominated deposits (FU-6B)

**Lithology in cores**

- peat
- humic clay
- clay
- (silty) clay loam
- silt loam
- loam
- sandy loam
- fine & medium sand
- coarse & very coarse sand
- gravel
- humic sand
- clay pebbles

ripened soil  
organic soil level  
dike
