Prompt $K_S^0$ production in $pp$ collisions at $\sqrt{s} = 0.9$ TeV

LHCb Collaboration

1. Introduction

Strangeness production studies provide sensitive tests of soft hadronic interactions, as the mass of the strange quark is of the order of $\Lambda_{QCD}$. Strange-hadron production is suppressed, as a consequence, but still occurs in the non-perturbative regime. The hadronic production of $K_S^0$ mesons has been studied by several experiments at a range of different centre-of-mass energies, both in $pp$ and $p\bar{p}$ collisions (see for example [1–7]). The most recent measurements of $K_S^0$ production at the Tevatron have shown deviations with respect to the expectations of hadronization models [6]. Strangeness production is also a topic of great interest in heavy ion physics, and measurements of this process in $pp$ and $p\bar{p}$ collisions serve as reference point [7].

In this Letter measurements of prompt $K_S^0$ production are presented using data collected with the LHCb detector in $pp$ collisions at $\sqrt{s} = 0.9$ TeV, during the 2009 pilot run of the Large Hadron Collider (LHC). A $K_S^0$ is defined to be prompt if it is directly produced in the $pp$ collision, or if it appears in the decay chain of a non-weakly-decaying resonance (such as $K^+$) directly produced in the $pp$ collision. The measurements are made in the rapidity interval $2.5 < y < 4.0$ and down to below 0.2 GeV/c transverse momentum with respect to the beam line. This is a region not explored at this energy by any previous experiment, and is complementary to the coverage of other LHC experiments. The determination of the prompt $K_S^0$ production cross-section is normalized using an absolute measurement of the luminosity that relies on knowledge of the beam profiles.

The Letter is organized as follows. Section 2 gives a brief description of the LHCb detector and the configuration used to record data in December 2009 during the LHC pilot run. Section 3 gives an overview of the analysis strategy, the details of which are presented in the three following sections. Section 4 is dedicated to an explanation of the luminosity measurement. Section 5 presents the $K_S^0$ candidate selection and Section 6 the determination of the $K_S^0$ trigger and reconstruction efficiencies. The final results are discussed in Section 7 and compared with model expectations, before concluding in Section 8.

2. LHCb detector and 2009 data sample

The LHCb detector is a single-arm magnetic dipole spectrometer with a polar angular coverage with respect to the beam line of approximately 15 to 300 mrad in the horizontal bending plane, and 15 to 250 mrad in the vertical non-bending plane. The detector is described in detail elsewhere [8]. All subdetectors were fully operational and in a stable condition for the data that are analysed. For the measurements presented in this Letter the tracking detectors and trigger strategy are of particular importance.

A right-handed coordinate system is defined with its origin at the nominal $pp$ interaction point, the $z$ axis along the beam direction and $x$ and $y$ transverse to the beam.
line and pointing towards the magnet, and the $y$ axis pointing upwards. Beam-1 (beam-2) travels in the direction of positive (negative) $z$.

The LHCb tracking system consists of the Vertex Locator (VELO) surrounding the $pp$ interaction region, a tracking station (TT) upstream of the dipole magnet, and three tracking stations (T1–T3) downstream of the magnet. Particles traversing from the interaction region to the downstream tracking stations experience a bending-field integral of 3.7 Tm on average.

The VELO consists of silicon microstrip modules, providing a measure of the radial and azimuthal coordinates, $r$ and $\phi$, distributed in 23 stations arranged along the beam direction. The first two stations at the most upstream $z$ positions are instrumented to provide information on the number of visible interactions in the detector at the first level of the trigger (‘pile-up detector’). The VELO is constructed in two halves (left and right), movable in the $x$ and $y$ directions so that it can be centred on the beam. During stable beam conditions the two halves are located at their nominal closed position, with active silicon at 8 mm from the beams, providing full azimuthal coverage. During injection and beam adjustments the two halves are moved apart horizontally to a retracted position away from the beams.

The TT station also uses silicon microstrip technology. The downstream tracking stations T1–T3 have silicon microstrips in the region close to the beam pipe (Inner Tracker, IT), whereas straw tubes are employed in the outer region (Outer Tracker, OT).

During the 2009 run, low intensity beams collided in LHCb at the LHC injection energy, corresponding to a total energy of 0.9 TeV. Due to the dipole magnetic field the beams have a crossing angle that results in the $pp$ centre-of-mass frame moving with velocity $0.0021c$ in the $-x$ direction. Both the beam sizes and crossing angle were larger than those designed for high-energy collisions. In order not to risk the safety of the VELO, the 2009 data were recorded with the two VELO halves positioned 15 mm away from their nominal data-taking position (VELO partially open), resulting in a reduced azimuthal coverage. For this run, the magnetic dipole field was pointing downwards.

The bulk of the data presented here were collected in a series of LHC fills with the following two sets of beam conditions. The first configuration contained four bunches per beam, spaced by more than 8 $\mu$s, with two colliding and two non-colliding bunches, and a total peak beam intensity of about $10^{10}$ protons per bunch. The second configuration contained 16 bunches per beam, spaced by more than 2 $\mu$s, with eight colliding and eight non-colliding bunches, and a total peak beam intensity of about $1.3 \times 10^{10}$ protons per bunch. The nominal LHC injection optical function at the interaction point was used ($\beta^* = 10 \text{ m}$).

A trigger strategy was deployed to provide high efficiency for $pp$ inelastic interactions and for beam collisions with the residual gas in the vacuum chamber. The latter class of events is a necessary ingredient for the luminosity analysis. Events were collected for three bunch-crossing types: two colliding bunches ($bb$), beam-1 bunch with no beam-2 bunch ($b_1$), and beam-2 bunch with no beam-1 bunch ($b_2$). The first two categories of crossings, which produce particles in the forward (+$z$) direction, were triggered using calorimeter information: a $2 \times 2$ cluster with more than 240 MeV of transverse energy in the Hadron Calorimeter (HCAL) and at least three hits in the 6016 cells of the Scintillator Pad Detector (SPD) at the entrance to the calorimeter were required. Events containing a track in the muon system with transverse momenta above 480 MeV/$c$ were also triggered. Crossings of the type $b_2$, which produce particles in the backward direction only, were triggered by demanding a hit multiplicity of more than seven in the pile-up detector.

The visible collision rate for a single bunch pair was about 10 Hz and the acquired $b_1$ ($b_2$) rate for a single bunch was approximately 0.015 Hz (0.002 Hz), in agreement with the measured residual pressure and VELO acceptance. A sample of 424,193 events triggered in $bb$ crossings is used in the $K_S^0$ analysis.

### 3. Analysis strategy

All $K_S^0$ candidates are reconstructed in the $\pi^+\pi^-$ decay mode, using only events triggered by the calorimeter. Contributions from secondary interactions in the detector material or from the decay of long-lived particles are suppressed by requiring the $K_S^0$ candidates to point back to the $pp$-collision point. No attempt is made to separate the contributions from $K_S^0$ mesons produced in diffractive and non-diffractive processes.

Due to the long $K_S^0$ lifetime and partially open VELO position, only a small fraction of the $K^0_S$ daughter tracks traversing the spectrometer leave a signal in the VELO. Therefore, two paths are followed for the $K_S^0$ reconstruction and selection:

**a) Downstream-track selection:** Tracks reconstructed only with hits in the TT and T1–T3 stations (called downstream tracks) are combined, without using the VELO. The origin of the $K_S^0$ is taken as the point on the $z$ axis that is closest to the reconstructed flight vector of the $K_S^0$ candidate. This point is taken as an estimate of the primary vertex (PV), and is referred to as the ‘pseudo-PV’.

**b) Long-track selection:** $K_S^0$ candidates are formed with tracks leaving hits in the VELO and in the T stations (called long tracks). If available, measurements in the TT are added to the tracks. The PV is reconstructed from tracks seen in the detector, using VELO information whenever available.

The analysis is performed in bins of $K_S^0$ phase space. The kinematical variables used are the $K_S^0$ transverse momentum $p_T = \sqrt{p_x^2 + p_y^2}$ and the rapidity $y = \frac{1}{2} \ln((E + p_z)/(E - p_z))$, where $(E, \vec{p})$ is the $K_S^0$ four-momentum in the $pp$ centre-of-mass system. For a given bin $i$ in $p_T$ and $y$, the prompt $K_S^0$ production cross-section is calculated as

$$\sigma_i = \frac{N_{i}^{\text{obs}}}{\epsilon_i^{\text{trig/sel}}} \cdot \frac{\epsilon_i^{\text{sel}}}{L_{\text{int}}} \cdot \frac{N_{\text{prompt}}}{N_{i}^{\text{sel}}} \cdot \epsilon_i^{\text{sel}} \cdot L_{\text{int}},$$

where $N_{i}^{\text{obs}}$ is the number of observed $K_S^0 \rightarrow \pi^+\pi^-$ signal decays with reconstructed $p_T$ and $y$ in bin $i$, $\epsilon_i^{\text{trig/sel}}$ the reconstruction and selection efficiency, $\epsilon_i^{\text{sel}}$ the trigger efficiency on selected events, and $L_{\text{int}}$ the integrated luminosity. The number of signal events $N_{i}^{\text{obs}}$ is obtained from the mass distributions of the $K_S^0$ candidates.

The reconstruction and selection efficiency is estimated from a fully-simulated Monte Carlo (MC) sample of single $pp$ collisions as

$$\epsilon_i^{\text{sel}} = \frac{N_i^{\text{sel}}}{N_i^{\text{prompt}}},$$

where $N_i^{\text{sel}}$ is the number of $K_S^0 \rightarrow \pi^+\pi^-$ signal decays selected in the untriggered MC sample with reconstructed $p_T$ and $y$ in bin $i$ (extracted using the same procedure as in the data), and where $N_i^{\text{prompt}}$ is the number of generated prompt $K_S^0$ mesons with generated $p_T$ and $y$ in bin $i$. This efficiency includes the geometrical acceptance, as well as the reconstruction and selection efficiencies. It also incorporates all corrections related to the following effects: secondary interactions of $K_S^0$ in the material, $K_S^0 \rightarrow \pi^+\pi^-$ branching fraction, decay in flight and secondary interaction of the decay
products, non-prompt $K_S^0$ production and finite resolution of the $p_T$ and $y$ observables.

The trigger efficiency is estimated using the same MC events. However, since the efficiency depends on the global event properties, the MC events are weighted to reproduce the observed track multiplicity in the selected signal events. Then

$$
\epsilon_{\text{trig/sel}} = \frac{Y_{\text{trig/sel}}}{Y_{\text{sel}}}
$$

is computed, where $Y_{\text{trig/sel}}$ and $Y_{\text{sel}}$ are the weighted MC signal yields extracted after and before the trigger cuts are applied.

The integrated luminosity $L_{\text{int}}$ is determined using a novel 'beam imaging' method [9], taking advantage of proton collisions with the residual gas in the interaction region and of the excellent vertexing capability of the VELO. The beam profiles and positions are determined with the LHC machine instrumentation, enabling an absolute normalization of the luminosity. The total luminosity is then obtained as the sum of the estimates for each pair of colliding bunches in the machine.

The beam crossing angle is limited to the horizontal plane. No correlation between the transverse coordinates is observed at the level of precision needed for this analysis, thus the $x$ and $y$ projections can be factorized. The bunch shapes are well described by Gaussian distributions in all three dimensions, characterized in the $x$-$y$ plane at the time of crossing by their width $\sigma_{ij}(j=x,y)$ and by their average longitudinal width $\sigma_z$, assumed to be equal for both beams. With these approximations and for small crossing angle, Eq. (4) can be rewritten as

$$
L = \frac{n_1 n_2 f}{2\pi \sqrt{1+2(\theta \sigma_z)^2/\sigma_x^2}} \prod_{j=x,y} \frac{1}{\sqrt{\sigma_{ij}^2 + \sigma_z^2}} \times \exp\left(-\frac{1}{2} (\mu_{ij} - \mu_{2j})^2 / \sigma_{ij}^2 + \sigma_z^2\right).
$$

The observables $\sigma_{ij}$ and $\mu_{ij}$ are extracted from the transverse distributions of the beam–gas vertices reconstructed in the $bb$ crossings of the colliding bunch pair with a z coordinate satisfying $-1000 < z < -200$ mm ($200 < z < 1000$ mm) for $i = 1$ ($i = 2$). These transverse distributions are obtained by projecting the reconstructed vertex positions onto a plane perpendicular to the corresponding beam direction. As illustrated in Fig. 1, the beam directions, and hence also the half crossing angle $\theta$, are obtained from straight-line fits through the measured positions of vertices reconstructed in $b1$ and $b2$ crossings of other non-colliding bunches. The observed half crossing angle of $\theta = 2.1 \pm 0.1$ mrad in the horizontal plane is in agreement with the expected value.

In addition, the distribution of $pp$-collision vertices, produced by the colliding bunch pair and identified by requiring $-150 < z < 150$ mm, can be used to measure the parameters of the luminous region. Its position $\mu_j$ and transverse width $\sigma_j$,

$$
\mu_j = \frac{\mu_{1j}\sigma_{2j}^2 + \mu_{2j}\sigma_{1j}^2}{\sigma_{1j}^2 + \sigma_{2j}^2} \quad \text{and} \quad \sigma_j^2 = \frac{\sigma_{1j}^2 \sigma_{2j}^2}{\sigma_{1j}^2 + \sigma_{2j}^2} (j = x, y)
$$

are determined with the LHC machine instrumentation, enabling an absolute normalization of the luminosity.
can be used to constrain the bunch observables. Owing to the higher statistics of pp collisions compared to beam–gas interactions, the constraints of Eq. (6) provide the most significant input to the overlap integral.

The longitudinal bunch size $\sigma_z$ is extracted from the longitudinal distribution of the pp-collision vertices. Because $\sigma_z$ is approximately 200 times larger than $\sigma_x$, the crossing angle reduces the luminosity by a non-negligible factor equal to the first square root term in Eq. (5). For the fill used to determine the absolute luminosity, this factor is estimated to be $1.087 \pm 0.012$.

The vertex resolutions need to be measured since they are of the same order as the bunch sizes. This is achieved by comparing, on an event-by-event basis, the reconstructed vertex positions obtained from two independent sets of tracks. In each event, the sample of available tracks is randomly split into two sets of equal multiplicity, and the event is kept only if exactly one vertex is reconstructed for each set. In this case the two vertices are assumed to originate from the same interaction. The vertex resolution for each coordinate is obtained as the width of the distribution of the difference in position between the two reconstructed vertices divided by $\sqrt{2}$. A systematic study of the vertex resolutions in both $x$ and $y$ is then performed as a function of the number of tracks $N$ contributing to the vertex, of the crossing type, and of the $z$ coordinate of the vertex. The resolution functions are found to be well parametrized by a double Gaussian function

$$ R_j(N,z) = f_j G(s_j(N,z)) + (1-f_j) G(s_j(N,z)/r_j) $$

(j = x, y),

where $f_j$ is the fraction of events in the first Gaussian function, $r_j$ is the ratio of the widths of the two Gaussian functions, and $G(s_j(N,z))$ is a Gaussian function centred at zero with width $s_j^{\text{track}}(N,z) = N^{-0.5+\delta_j/N^2}s_j^{\text{track}}$ for beam–beam,

$$ s_j^b(N,z) = (b_{ij} + m_{ij})s_j^{bb}(N,z) $$

for beam–gas (i = 1, 2)

(j = x, y).

The parameters $s_j^{\text{track}}$ describe the per-track resolutions, $\delta_j$ specify the dependence on the number of tracks, while $b_{ij}$ and $m_{ij}$ model the linear $z$ dependence for beam–gas vertices. The validity of this parametrization has been verified with MC simulation studies. The systematic uncertainties on the parameters are estimated from the level of agreement in that check. The final set of resolution parameters is given in Table 1. The resolution is found to be better in $y$ than in $x$, which is expected from the partial VELO opening described in Section 2.

For both transverse coordinates, each sample of vertices (defined for every colliding bunch pair in each fill) is fitted with convolutions of the Gaussian beam shapes with the resolution function of Eq. (7). This fit is performed with all three types of interactions. With the constraints of Eq. (6), this yields directly the position $\mu_{ij}$ and Gaussian width $\sigma_{ij}$ of the underlying distributions. Some example distributions are shown in Fig. 2. The systematic errors on the results are estimated by varying the resolution parameters within their total uncertainties.

The remaining ingredients needed for the direct luminosity measurement are the bunch intensities. The LHC is equipped with two systems of beam current transformers (BCT) [11]. A DC–BCT system provides an ungated measurement of the total beam current, while a fast-BCT system is gated to measure the current induced on a bunch-by-bunch basis. The individual bunch intensities are obtained from these fast-BCT readings, but constraining their sum to the DC–BCT measurements. At the low intensities of the 2009 pilot run, the offset in the DC–BCT digitization is non-negligible and is corrected by averaging the readings in the periods without circulating beam just before and after a fill.

The method described above was used to measure the luminosity in four different machine fills. Two of those fills were relatively

short and the third was taken before optimization of the beam alignment. The remaining fill, taken under optimal conditions and representing approximately 25% of the sample used for the $K_S^0$ production study, is chosen to determine the absolute normalization of the luminosity for the 2009 LHC pilot run. The limiting uncertainty on this result comprises contributions from the measurements of the beam intensities (12%), widths (5%), relative positions (3%) and crossing angle (1%). This is the most precise determination of the beam intensities expected to improve in the future.

5. $K_S^0$ selection and signal extraction

In the downstream-track selection, a $K_S^0$ candidate is formed from any combination of two oppositely-charged downstream tracks, assumed to be pions, satisfying the requirements listed in the top part of Table 2. The pseudo-PV was defined in Section 3, and $\theta_{\text{pointing}}$ is the angle between the $K_S^0$ momentum vector and the direction joining the pseudo-PV and the $K_S^0$ decay vertex.

In the long-track selection, primary vertices are reconstructed from at least three tracks. Each $K_S^0$ candidate formed from long tracks is associated with the PV that minimizes its impact parameter and the requirements listed in the bottom part of Table 2 are applied. The variable $v$ is similar to a Fisher discriminant formed with the logarithms of the impact parameters; it is defined as $v = \ln(|I_1 - I_0|/|I_0 I_1|)$. Here $I_1$, $I_0$ and $I_0$ are the impact parameters of each of the two tracks and of the $K_S^0$ candidate with respect to their closest PV, respectively, and the value of $I_1$ is fixed to 1 mm.

Mass distributions are obtained for both $bb$ crossings and $b1$ crossings. In order to keep only the contribution arising from $pp$ collisions, the $b1$ mass distribution is subtracted, after proper normalization, from the $bb$ mass distribution. The normalization factor is $0.908 \pm 0.015$, averaged over the entire sample used for this analysis. It is obtained from the ratio of the number of interaction vertices reconstructed in $bb$ and $b1$ crossings in the region $z < -200$ mm where no $pp$ collision can take place. This beam-gas subtraction removes about 1.2% of the $K_S^0$ signal.

The beam–gas subtracted mass distributions are shown in Fig. 3 for all selected $K_S^0$ candidates. A $\chi^2$ fit is made, describing the background with a linear function and the signal with the sum of two Gaussian functions of common mean value, with all parameters left free. It gives a total $K_S^0$ signal yield of $4801 \pm 84 (1140 \pm 35)$, a mean mass value of $497.12 \pm 0.14$ MeV/c$^2$ ($497.43 \pm 0.14$ MeV/c$^2$), and an average resolution of $9.2$ MeV/c$^2$ ($5.5$ MeV/c$^2$) for the downstream-track (long-track) selection. Quoted uncertainties are statistical only. The mass values are close to the known $K_S^0$ mass value of $497.61 \pm 0.02$ MeV/c$^2$ [12], reflecting the current status of the mass-scale calibration. In the long-track selection, the statistics are lower than in the downstream-track selection, but the background level is lower and the mass resolution is significantly better.

The beam–gas subtraction and signal yield extraction are repeated for each bin in $p_T$ and $y$, leading to the results shown in Table 3. The systematic uncertainties on the extraction of these yields are obtained by comparing the yields from single and double Gaussian signal fits and from side-band subtraction to the expected yield in a Monte Carlo sample of comparable statistics to the data set. Additionally the fitted and side-band subtracted yields are compared, and an alternate (exponential) background model is used in the mass fits. The largest observed deviation in any of these studies is taken as systematic uncertainty. For the long-track selection, where the yields are lower, the central value is obtained from the side-band subtraction method assuming a linear background.

![Fig. 3. Mass distributions of all selected $K_S^0$ candidates, in the downstream-track (left) and long-track (right) selections. The points are the beam–gas subtracted data and the curves are the result of the fits described in the text.](image-url)
6. Efficiency estimation

A sample of fully simulated events is used to estimate the reconstruction and selection efficiency $\epsilon_{\text{sel}}$ in each $p_T$ and $y$ bin. Single $pp$ collisions are generated with the PYTHIA 6.4 program [13] and the generated particles are tracked through the detector with the GEANT 4 package [14], taking into account the details of the geometry and material composition of the detector. The simulation of the detector response is tuned to reproduce test beam results [8]. In terms of dead and noisy channels, the simulation reflects the detector status of the data set used in this analysis.

Residual misalignments of the tracking stations and edge-effects of cell efficiencies in the Outer Tracker are not perfectly described in the MC sample, resulting in an overestimation of the tracking efficiency. To incorporate these effects, we compare for each detector unit the hit content of the tracks in the data and MC samples and randomly remove hits in the simulation until we achieve agreement in all subdetector components and phase-space regions. The MC sample modified in this way is the nominal MC sample, used throughout the analysis.

To assign systematic uncertainties on the efficiencies obtained in this MC sample the single track-finding efficiencies were measured. The VELO efficiency is obtained by using reconstructed tracks in the TT and in the T1–T3 stations and checking for an associated track segment in the VELO. Similarly the TT and T1–T3 station efficiencies are tested by reconstructing tracks using VELO and HCAL information. For downstream tracks with a $p_T$ larger than 0.2 GeV/c agreement between the track-finding efficiencies in data and in the Monte Carlo sample is observed within the statistical uncertainties of approximately 3%. Below 0.2 GeV/c, the ratio of efficiencies in data and MC is found to be 0.85 ± 0.12. As a conservative approach 3% (15%) uncertainties for the reconstruction efficiency of tracks with a $p_T$ larger (smaller) than 0.2 GeV/c are assigned. Propagating these uncertainties to the $K_0^S$ reconstruction efficiency results in correlated systematic uncertainties of up to 17% for the lowest $K_0^S$ $p_T$ bins of the downstream-track selection.

The systematic uncertainty on the $K_0^S$ selection efficiency is obtained by comparing, in data and MC, the selection efficiency relative to a preselection. This preselection is close to 90% efficient for downstream-track selected signal events in MC.

If the reconstruction and selection efficiency varies strongly within a given bin of phase space, the average value estimated with MC will depend on the assumed production spectrum within the bin. The extraction of the efficiency-corrected yield in each bin is therefore repeated using efficiencies in four sub-bins rather than an average efficiency, and the difference with respect to the nominal result is taken as an uncorrelated systematic uncertainty. The size of this effect varies between 0 and 20%. The largest uncertainties are obtained in bins at the limit of the acceptance.

The fraction of non-prompt $K_0^S$ signal in the selected MC sample is found to be 0.6%. By definition, this is corrected for in the efficiencies defined in Eq. (2). Because the correction is so small, even doubling this contribution would have no significant impact on the final result. Similarly, the systematic uncertainty due to material interactions, assuming a conservative ±10% variation of the known detector material, is found to be negligible.

The trigger efficiency $\epsilon_{\text{trig}}^{\text{HLT/SEL}}$ for selected signal events depends on the track multiplicity. As outlined in Section 3, $\epsilon_{\text{trig}}^{\text{HLT/SEL}}$ is obtained after weighting the previously-defined nominal MC sample in order to reproduce, in selected signal events, the track multiplicity observed in the data (see Fig. 4 (left)). This re-weighting is only applied for the determination of the trigger efficiency, as the reconstruction and selection efficiency has been shown not to de-

depend on the track multiplicity. The trigger efficiency is found to be
greater than 95% in every phase-space bin. As a cross check, it is also
extracted directly from data, using a method that exploits the fact that signal events can be triggered by the $K^0_S$ daughters
(trigger on signal, TOS) or by the rest of the event (trigger independent
of signal, TIS), with a very large overlap between the two cases. Assuming that the two ways to trigger are independent, $N_{TIS\Rightarrow TOS} = \epsilon_{TIS\Rightarrow TOS}N_{sel} = N_{TIS}N_{TOS}/N_{sel}$, where, in a given region of phase space, $N_{TIS}$ and $N_{TOS}$ are the number of TIS and TOS events, $N_{TIS\Rightarrow TOS}$ is the number of events which are simultaneously both TIS and TOS, and $N_{sel}$ is the number of selected signal events. Hence

$$
\epsilon_{\text{trig/sel}}^{\text{data}} = \frac{N_{TIS\Rightarrow TOS}}{N_{sel}} = \frac{N_{TIS}N_{TOS}/N_{sel}}{N_{TIS}N_{TOS}},
$$

where $N_{TIS\Rightarrow TOS}$ is the number of events which are triggered either as TIS or TOS. Due to the limited data statistics, a significant comparison between data and MC can only be done in bands of $p_T$ or $y$, rather than in 2-dimensional bins. Good agreement is found, as illustrated in Fig. 4 (right), and the observed differences are translated into a global correlated systematic uncertainty of 2%.

The dependence on the modeling of diffractive processes is studied per bin of phase space by changing the fraction of diffractive events in the PYTHIA 6.4 sample by 50% of its value, and by replacing these events with diffractive events generated with PYTHIA 8.1 [15].\(^1\) The evaluation of the MC efficiencies is repeated for different PYTHIA 6.4 parameter values [17], leading to no significant change.

There are two important differences in the analysis of the $K^0_S$ candidates from the long-track selection relative to the downstream-track selection. Firstly, a reconstructed PV is required in the former case, so the systematic uncertainty on the PV reconstruction efficiency needs to be assessed. The simulation is found to be in good agreement with the data, but the analysis is more sensitive to the contribution from diffractive events. Secondly, the background level in the long-track selection is significantly lower than in the downstream-track selection, due to the PV requirement and the precise VELO measurements. Therefore it is possible to remove the minimum $p_T$ requirement on the $K^0_S$ daughters in the long-track selection. This allows the extension of the analysis to two low $p_T$ bins in the range $2.5 < y < 3.0$, which are inaccessible to the downstream-track selection. The dominant systematic error for these two bins is from the large uncertainty on the tracking efficiency for the very low $p_T$ $K^0_S$ daughters.

The estimates of the total efficiencies $\epsilon_{\text{trig/sel}}^{i} \times \epsilon_{\text{sel}}^{i}$ are given in Table 4. The various contributions to the uncertainties have been classified according to their correlations across bins, as shown in Table 5, and added in quadrature.

Sources of uncertainty on the $K^0_S$ production cross-sections of Eq. (1), with relative values quoted for the downstream-track selection. A range of values means that the uncertainty was evaluated per bin of ($p_T$, $y$) phase space (with extreme values quoted), while a single value indicates a global uncertainty assumed to be bin-independent. The different contributions are classified as uncorrelated or (at least partially) correlated across the different bins.

Fig. 5. Double-differential prompt $K_S^0$ production cross-section in $pp$ collisions at $\sqrt{s} = 0.9$ TeV as a function of transverse momentum $p_T$ and rapidity $y$. The points represent LHCb data, with total uncertainties shown as vertical error bars and statistical uncertainties as tick marks on the bars. The histograms are predictions from different settings of the PYTHIA generator (see text). The lower plots show the MC/data ratios, with the shaded band representing the uncertainty for one of these ratios, dominated by the uncertainty on the measurements (the relative uncertainties for the other ratios are similar).

- the LHCb settings, which include only soft diffraction as described by PYTHIA 6.4 (red solid histogram);
- the LHCb settings where diffractive processes have been switched off (blue dotted histogram);
- the “Perugia 0” settings [17], which exclude diffraction (green dashed histogram).

The predictions agree reasonably well with the data, although they tend to underestimate (overestimate) the measured production in the highest (lowest) $p_T$ bins.

Previous measurements of the prompt $K_S^0$ cross-section in high-energy $pp$ collisions, performed by UA5 [2], UA1 [5] and CDF [4] at different centre-of-mass energies and in different rapidity or pseudo-rapidity regions, have been published in the form of invariant differential cross-sections $d^2\sigma/(dp_Tdy)$ as a function of $p_T$. We convert these into measurements of $d^2\sigma/(dp_Tdy)$ by multiplication with $2\pi p_T$, and compare them with our results in Fig. 6, lim-

8. Conclusions

Studies of prompt $K_0^0$ production at $\sqrt{s} = 0.9$ TeV have been presented, made with the LHCb detector using the first pp collisions delivered by the LHC during 2009. The data sample used corresponds to an integrated luminosity of $6.8 \pm 1.0 \mu b^{-1}$, a value which has been determined using measurements of the beam profiles that exploit the high precision of the VELO. This is the most precise determination of the luminosity for the 2009 LHC pilot run, only limited by the uncertainties on the beam intensity.

The differential cross-section has been measured as a function of $p_T$ and $y$, over a range extending down to $p_T$ less than 0.2 GeV/$c$, and in the rapidity interval $2.5 < y < 4.0$, a region that has not been explored in previous experiments at this energy. These results show reasonable consistency with expectations based on the PYTHIA 6.4 generator, and should provide valuable input for the future tuning of Monte Carlo generators.

Acknowledgements

We express our gratitude to our colleagues in the CERN accelerator departments for the excellent performance of the LHC. The valuable contribution of J.-J. Gras (CERN) to the analysis of the LHC beam current measurements is gratefully acknowledged. We thank the technical and administrative staff at CERN and at the LHCb institutes, and acknowledge support from the National Agencies: CAPES, CNPq, FAPERJ and FINEP (Brazil); CERN; NSFC (China); CNRS/IN2P3 (France); BMBF, DFG, HGF and MPG (Germany); SFI (Ireland); INFN (Italy); FOM and NWO (Netherlands); SCRR (Poland); ANCS (Romania); MinES of Russia and Rosatom (Russia); MICINN, XUNGAL and GENCAT (Spain); SNSF and SER (Switzerland); NAS Ukraine (Ukraine); STFC (United Kingdom); NSF (USA). We also acknowledge the support received from the ERC under FP7 and the Région Auvergne.
