Chapter 5.2

Interferon- α and the calcifying microangiopathy in Aicardi-Goutières syndrome

MD Klok, HS Bakels, NL Postma, RML van Spaendonk, MS van der Knaap and M Bugiani

Ann Clin Transl Neurol, 2015 (in press)

Abstract

Aicardi-Goutières syndrome is a leukoencephalopathy with calcifications and increased cerebrospinal fluid interferon- α . The relation between interferon- α and brain pathology is poorly understood. We report a patient with mutations in the disease-associated gene *SAMHD1*. Neuropathology showed an extensive microangiopathy with calcifications consistently associated with blood vessels. In an *in vitro* model of the microangiopathy, interferon- α enhanced vascular smooth muscle cell-derived calcifications. The non-infarcted white matter harbored apoptotic oligodendrocytes and increased numbers of oligodendrocyte progenitors. These findings better define the white matter pathology and provide evidence that interferon- α plays a direct pathogenetic role in the calcifying angiopathy typical of this disease.

Introduction

Aicardi-Goutières syndrome (AGS; OMIM 225750) is an inherited leukoencephalopathy characterized by calcifications in the white matter, basal ganglia and thalami, and increased cerebrospinal fluid (CSF) interferon (IFN)- α with lymphocytosis (Aicardi & Goutières, 1984; Crow, 2013). AGS is clinically heterogeneous. The classic severe form begins in the first months with psychomotor delay, feeding difficulties, irritability, episodes of aseptic febrile illness, and chilblain skin lesions. Symptoms progress over months to years with secondary microcephaly, brain atrophy and spastic tetraparesis, and then stabilize. Death usually occurs before the age of ten years. Milder forms have onset after the first year and show slower progression and longer survival (Crow, 2013).

AGS is genetically heterogeneous. About 90% of patients have mutations in any of seven genes (*TREX1*, *RNASEH2B*, *RNASEH2C* and *RNASEH2A*, *SAMHD1*, *ADAR1* and *IFIH1*) leading to a perturbation of the innate immune response with increased intrathecal production of the IFN-type I cytokine IFN- α (Hofer & Campbell, 2013; Diamond, 2014). Typical neuropathological findings include brain atrophy, lack of myelin, vascular changes, infarctions, and calcifications (Barth et al., 1999; Goutières et al., 1998; Kumar et al., 1998).

We report the neuropathology of an AGS patient. The observation of calcifications consistently associated with blood vessels prompted us to investigate *in vitro* if IFN- α promotes a calcifying phenotype in vascular smooth muscle cells (VSMCs).

Patient and Methods

The patient was a girl with early-infantile severe encephalopathy and later also chill blains. CSF analysis at age 1 year revealed pleocytosis (61 cells/mm³, normal <3/mm³) and increased IFN- α (37 IU/ml, normal <2 IU/ml). Imaging studies at 3 years showed bilateral signal change and atrophy of the cerebral white matter, and calcifications in the basal ganglia and periventricular regions (fig. 1A,B). Repeated imaging at 5 and 11 years showed attenuation of the white matter signal abnormalities and a new lesion in the left frontal cortex (fig. 1C,D). The patient died at 17 years during pneumonia. The clinical picture, imaging and laboratory data were typical of AGS. Genetic analysis revealed compound-heterozygous mutations in *SAMHD1* (p.Met216fs and p.Arg408Pro). The first mutation is a null-mutation; the second mutation results in an amino acid change affecting a residue poorly conserved amongst species. The mutation is not listed in the 1000 Genomes

Figure 1. Imaging findings. (A) Axial CT scans at age 3 years demonstrate focal calcifications in the periventricular white matter and subtle finely dispersed calcifications in the basal nuclei (*arrows*). (B-D) MRI axial T2-weighted images at age 3 years (B) shows diffuse high signal in the cerebral white matter extending frontally into the subcortical regions as well as white matter atrophy. Serial scans at 5 (C) and 11 years (D) reveal attenuation of the white matter signal changes and focal involvement of the cortex in the left more than right frontal lobe (D).

database (www.1000genomes.org), making it unlikely that it represents a common polymorphism. Conventional prediction programs are heavily influenced by inter-species amino acid conservation and do not confirm, but also do not exclude pathogenicity. However, proline has an exceptional conformational rigidity and *in silico* analysis suggests an effect on the tertiary structure of the protein and possibly on tetramer formation. The patient had one healthy and two affected siblings; the mutations segregated with the disease in the family.

Neuropathology

Brain tissue of the patient and three age-matched controls without confounding neuropathology was obtained with informed consent within 5 hours post-mortem. Formalin-fixed, paraffin-embedded tissue sections were routinely stained with Hematoxylin & Eosin (H&E) and immunostained as described (Kevelam et al., 2013) for proteolipid protein (PLP; AbDSerotec, 1:3000), glial fibrillary acidic protein (GFAP; Millipore, 1:1000), smooth muscle actin (SMA; Dako, 1:200), IFN- α (PBL Biochemical Labs, 1:100), CD31 (Dako, 1:50), CD3 (Dako, 1:100), CD68 (Dako, 1:3000), HLA-DR (Abcam, 1:50) and caspase3 (Dako, 1:500). Fluorescence immunohistochemistry was performed on cryosections as described (Bugiani et al., 2013) against oligodendrocyte transcription factor 2 (olig2; Abcam, 1:400) and platelet-derived growth factor receptor α (PDGFR α ; BD Pharmingen, 1:100). Known positive controls and negative controls by omitting the primary antibody were included to verify specificity of immunohistochemical labelling. Images were acquired on a Leica DM6000B microscope (Leica Microsystems). Control tissue was employed for selected stains and to compare oligodendrocyte lineage cell numbers and apoptotic cells in the white matter. Caspase3-, PDGFR α - and Olig2-immunopositive cells were counted individually in 10 fields using a 20x objective, expressed as percentage of the total number of oligodendrocytes or nuclei and compared using an independent-samples *t*-test.

Mineralization assay

Human VSMCs (hVSMCs) isolated from umbilical artery explants were grown on 0.1% gelatin-coated (Sigma) 6-well plates in culture medium supplemented with 20% 1:1 heat-inactivated fetal calf serum (FCS, Hyclone, Bodinco)/human serum (Millipore), as described (Proudfoot & Shanahan, 2012). SMA-immunoreactivity confirmed hVSMC identity (not shown). For the mineralization assay, fresh (1 experiment, 2 donors, 5.000 cells/well) or frozen (2 experiments, 1 donor each, passage 2 or 3, 20.000 cells/well) hVSMCs were grown on gelatin-coated 96-well plates until 80-90% confluence. Following standard methods with minor adjustments (Reynolds et al., 2004), mineralization was induced in culture medium containing 1% FCS/human serum (1:1) and a concentration gradient of calcium (0.0, 0.9, 1.3, 2.0, 3.0, 4.4, 6.7 and 10mM CaCl₂; mammalian extracellular calcium range 1.2-1.6mM [Jones & Keep, 1988]) with or without IFN- α 2b (100ng/ml or 200pg/ml, Miltenyi Biotec) for 3 weeks. Mineralization was detected with von Kossa or alizarin red staining as described (Bonewald et al., 2003; Proudfoot et al., 2000)

Figure 2. Neuropathology. (A, B) H&E stain show perivascular calcifications (purple) with a concentric pattern around blood vessels in the parietal white matter (A) and in the cerebellum (B). (C) Stain against smooth muscle actin (SMA, brown) of the cerebellar white matter shows that calcifications (blue) are located in the tunica media and lined by SMA-positive smooth muscle cells. Note that the normal SMA-immunoreactivity (upper right) is progressively lost coincident with increasing vessel calcification (lower left). (D) Stain against CD31 of the frontal white matter reveals that apparently perivascular small calcifications are often centered on a CD31-immunoreactive core (*arrowheads*). (E) At high magnification, glial fibrillary acidic protein (GFAP) stain of the frontal white matter shows reactive astrocytes, one of which is multinucleated (*arrowhead*). (F) In the same region, a multinucleated

and quantified by determining average pixel intensities per well using ImageJ (v1.44, imagej.nih.gov/ij/). For each condition, a third well was used to stain nuclei with Hoechst (H1399, Life Technologies, 0.2 µg/ml) to visualize cell density.

Results

Neuropathology

Brain weight was 750 g (mean normal for age: 1300 g). Inspection on sectioning showed mild white matter atrophy, numerous cortico-subcortical infarcts and small basal nuclei bleedings. No infarcts were detected in brainstem and cerebellum.

Microscopically, infarcts coincided with thrombotic occlusion of meningeal and intraparenchymal vessels. Microangiopathy was widespread in the striatum, cerebral white matter (fig. 2A) and cerebellum (fig. 2B). Small arterioles and precapillary vessels showed variably thickened tunica media and adventitia with focal or circular calcific deposits. Presence of calcifications coincided with loss of SMA-immunoreactivity in smooth muscle cells (fig. 2C). Notably, calcifications were always associated with blood vessels. Stain for the endothelial marker CD31 revealed that many microcalcifications apparently not adjacent to blood vessels were also centred on endothelial cells (fig. 2D).

In the non-infarcted cerebral white matter, GFAP stain revealed numerous reactive astrocytes, some of which multinucleated, that also expressed IFN- α (fig. 2E,F). No IFN- α -positive astrocytes were found in control white matter (fig. 2G). Stain against PLP showed mild lack of myelin with relative sparing of U-fibers (fig. 2H).

Figure 2 (cont.) astrocyte (*arrowhead*) shows a similarly intense IFN- α -immunoreactivity compared to mononucleated astrocytes. (G) Control frontal white matter shows no IFN- α -positive astrocytes. (H) Whole mount of a non-infarcted area in the frontal lobe stained against proteolipid protein (PLP) reveals mild lack of myelin in the deep white matter (*arrow*) compared to the U-fibers. (I) Stain against CD3 of the frontal white matter shows few infiltrating T-cells mostly restricted to the perivascular space. (J) Caspase3 stain of the same region reveals numerous immunoreactive cells with small, round nuclei and a perinuclear halo, compatible with apoptotic oligodendrocytes. (K) Caspase3-positive oligodendrocytes are virtually absent in control fronto-parietal white matter ($P<.0001$). (L) Cell counts of cells expressing the oligodendrocyte lineage-specific marker olig2 in the fronto-parietal white matter shows mild loss of oligodendrocytes in AGS compared to controls ($P=0.036$). (M) There are higher numbers of OPCs in the non-infarcted white matter of the AGS patient compared to the controls as revealed by platelet-derived growth factor α receptor (PDGFR α) immunoreactivity ($P<.0001$). Bars: (A, B, I and J) 50 µm, (C and D) 40 µm, (E-G) 30 µm. Bars in the graphs indicate the standard error of the mean.

Inflammatory signs were inconspicuous, with scarce HLA-DR- and CD68-positive activated microglia/macrophages (not shown) and CD3-positive T-lymphocytes (fig. 2I). To better characterize myelin pathology, we assessed oligodendrocyte lineage cell numbers in frontal and parietal white matter. Compared to controls, there was mild loss of olig2-positive oligodendrocytes ($P=.036$) with numerous caspase3-positive apoptotic cells ($P<.0001$) (fig. 2J-L); however, a count of cells expressing the oligodendrocyte progenitor cell (OPC) marker PDGFR α revealed that OPC numbers were markedly higher in AGS than in control white matter ($P<.0001$, fig. 2M).

Mineralization assay

Cultured hVSMCs underwent cumulative calcification induced by increasing concentrations of calcium in the medium (fig. 3A-C). Addition of IFN- α 2b enhanced hVSMC calcification at lower calcium concentrations in a dose- dependent manner. Notably, this effect was already evident at IFN- α 2b concentration of 200pg/ml, comparable to that in AGS patients' CSF (Goutières et al., 1998 ; Rubinstein et al., 1981 ; Hobbs & Pestka, 1982 ; van Heteren et al., 2008). Cultures of fresh or frozen hVSMCs gave comparable results.

Figure 3. IFN- α enhances calcification in cultured hVSMCs. (A) hVSMCs were exposed to increasing concentrations of calcium (0, 0.9, 1.3, 2 [shown], 3 [shown], 4.4 [shown], 6.7 and 10 mM CaCl₂), with or without IFN- α 2b (200 pg/ml or 100 ng/ml). Calcification was detected by von Kossa (gray-brown) or Alizarin red stain. IFN- α 2b promoted hVSMC calcification particularly at 2 and 3 mM calcium, with 100 ng/ml IFN- α 2b having a stronger effect than 200 pg/ml IFN- α 2b. Calcification was similar at calcium concentrations of 4.4 mM or higher, with IFN- α 2b having a small inducing effect. No calcification was detected at 1.3 mM calcium concentration or lower, with or without IFN- α . Representative results are shown for three comparable experiments. (B) Hundred-times magnification pictures of the hVSMCs cultured with 2 mM calcium, for the wells stained with Alizarin red (top) or for cell density with Hoechst (grayscale, bottom). (C) Calcification quantification of wells stained with von Kossa measured in average pixel intensity per well. An effect of IFN- α 2b was particularly detected at 3 mM CaCl₂, with an intensity increase of 20% with 200 pg/ml or 100 ng/ml IFN- α 2b compared to 0 ng/ml IFN- α 2b, or at 2 mM CaCl₂, with an intensity increase of 48% with 200 pg/ml IFN- α 2b or 76% with 100 ng/ml IFN- α 2b, respectively. Representative results are shown for three comparable experiments.

Discussion

The findings of wedge-shaped infarcts, inhomogeneous loss of myelin and dystrophic calcifications in and around small vessels led to the suggestion that AGS represents a primary microangiopathy (Barth et al., 1999). Neuropathology of our case confirms extended involvement of small vessels and widespread calcifications. Most calcifications were within vessel walls, surrounding CD31-expressing intimal endothelial cells and adjacent to SMA- positive smooth muscle cells. Calcifications apparently not associated with blood vessels also surrounded a CD31-immunoreactive core, implying that they represent completely occluded calcified small vessels. This suggests that the calcific deposits in AGS arise in vascular walls, in particular in smooth muscle cells of the tunica media.

Vascular calcification is a cell-mediated process associated with de-differentiation of smooth muscle cells to an osteoblast/chondrocytic phenotype (Proudfoot & Shanahan, 2012; Chen & Moe, 2012). Dedifferentiation coincides with loss of contractile properties and SMA-immunoreactivity, as observed in our patient.

Inflammation is a known risk factor for vascular calcification; innate immune response mediators, including cytokines and tumor necrosis factor α , induce calcification of vascular cells *in vitro* (Chen & Moe, 2012). Little is known about the mechanisms underlying the calcifying microangiopathy in AGS. To experimentally investigate a role for IFN- α , we established an *in vitro* model of AGS-microangiopathy using hVSMCs chronically exposed to IFN- α . At a concentration comparable to that in patient's CSF, IFN- α 2b enhanced calcification of cultured hVSMCs. This indicates that IFN- α promotes the generation of calcium deposits by smooth muscle cells and supports the proposition that IFN- α acts directly on vascular smooth muscle cells in AGS, thus contributing to the calcifying microangiopathy. A similar mechanism may operate in other brain disorders with excessive IFN- α , including congenital viral infections and autoimmune disorders like systemic lupus erythematosus, that feature neuropathological changes and calcifications evocative of AGS (Hofer & Campbell, 2013).

In AGS patients' brains, astrocytes produce the excessive IFN- α (van Heteren et al., 2008). Mice overexpressing IFN- α in astrocytes develop a leukoencephalopathy similar to AGS (Akwa et al., 1998). The myelin pathology has been related to overexpression of cathepsin-D in CSF lymphocytes, a pro-apoptotic factor with myelin-directed protease activity induced by IFN- α (Pulliero et al., 2013). CSF of our patient was not available to verify IFN- α and cathepsin-D levels, but astrocytic IFN- α expression and apoptotic loss of oligodendrocytes were

conspicuous in the white matter, whereas influx of lymphocytes was negligible. This points to mechanisms other than lymphocytic neurotoxicity in maintaining oligodendrocytic pathology in AGS, at least in older patients in whom CSF lymphocyte numbers have fallen to normal (Crow, 2013). In our patient's non-infarcted white matter, lack of myelin was only mild and associated with increased OPC numbers. No myelin-laden macrophages were found, excluding ongoing demyelination. These findings suggest that the OPCs actively proliferate in response to oligodendrocyte loss and can mature into myelin-forming cells. Such remyelination effort highlights a previously unrecognized repair potential in AGS, which is in line with the progressive attenuation of the MRI white matter signal abnormalities.

In conclusion, present evidence indicates that astrocyte-derived IFN- α directly contributes to the calcifying microangiopathy typical of AGS. Further *in vivo* and *in vitro* studies are warranted to understand if IFN- α exerts a direct effect also on oligodendrocytic pathology and OPC differentiation throughout the disease course.
