The full greenhouse gas balance of an abandoned peat meadow

This chapter was published as Hendriks, D. M. D., van Huissteden, J., Dolman, A. J., van der Molen, M. K.: The full greenhouse gas balance of an abandoned peat meadow. *Biogeosciences* 4: 411-424, 2007.

Abstract

Globally, peat lands are considered to be a sink of CO₂, but a source when drained. Additionally, wet peat lands are thought to emit considerable amounts of CH₄ and N₂O. Hitherto, reliable and integrated estimates of emissions and emission factors for this type of land cover have been lacking and the effects of wetland restoration on methane emissions have been poorly quantified. In this paper we estimate the full greenhouse gas (GHG) balance of a restored natural peat land by determining the fluxes of CO₂, CH₄ and N₂O through atmosphere and water, while accounting for the different Global Warming Potentials (GWP's).

The site is an abandoned agricultural peat meadow, which has been converted into a wetland nature reserve ten years ago, after which the water level was raised. GHG fluxes were measured continuously with an eddy covariance system (CO₂) and flux chamber measurements (CH₄ and N₂O). Meteorological and hydrological measurements were collected as well. With growing seasons of respectively 192, 168 and 129 days, the annual net ecosystem exchange of CO₂ (NEE) was -446 ± 83 g C m⁻² yr⁻¹ for 2004, -311 ± 58 g C m⁻² yr⁻¹ for 2005 and -232 ± 57 g C m⁻² yr⁻¹ for 2006. Ecosystem respiration (R_{eco}) was estimated as 869 ± 668 g C m⁻² yr⁻¹ for 2004, 866 ± 666 g C m⁻² yr⁻¹ for 2005 and 924 ± 711 g C m⁻² yr⁻¹ for 2006. CH₄ emissions from the saturated land and water surfaces were high compared to the relatively dry land. Annual weighted CH₄ emissions were 31.27 ± 20.40 g C m⁻² yr⁻¹ for 2005 and 32.27 ± 21.08 g C m⁻² yr⁻¹ for 2006. N₂O fluxes were too low to be of significance. The water balance of the area was dominated by precipitation and evapotranspiration and therefore fluxes of carbon and CH₄ through seepage, infiltration and drainage were relatively small (17.25 g C m⁻² yr⁻¹). The carbon-balance consisted for the largest part of CO₂ uptake, CO₂ respiration and CH₄ emission from water saturated land and water. CO₂ emission has decreased significantly as result of the raised water table, while CH₄ fluxes have increased since the water level raise. In GWP's the area was a small net GHG sink given as CO₂-equiv. of -71 g m⁻² yr⁻¹ (over a 100-year period).

3.1 Introduction

Human activities have caused an increase in atmospheric concentrations of GHG's since the pre-industrial era by 30% for CO₂, by 150% for CH₄ and by 17% for N₂O (IPCC, 2001). The European land surface is thought to be absorbing a significant amount of the current industrial CO₂ emissions (Janssens et al., 2005) and to be releasing over 40% of the European CH₄ and N₂O emissions (IPCC, 2001). However, reliable estimates of emissions and emission factors are still lacking.

Unlike industrial emissions, emissions related to land use are controlled by a combination of biological, climatological and management factors and show large spatial and temporal variability. To be able to understand the effects of the rising GHG concentrations in the atmosphere as well as the variability and vulnerability of the natural carbon cycle, knowledge of the emission and uptake of carbon by terrestrial surfaces is necessary.

Peat lands in Europe have formed a large sink of atmospheric CO₂ since the last glacial maximum. This is the result of their ability to accumulate organic matter at a higher rate than decomposition takes place, mainly as a result of high water tables and therefore anaerobic conditions. Due to these generally wet and anaerobic conditions peat lands are also significant emitters of the GHG CH₄ and sometimes N₂O (Drösler et al., in press 2007). The GWP's of CH₄ (~23, over 100 years) and N₂O (~300, over 100 years) are significantly higher than that of CO₂ (1 by definition) (IPCC, 2001).

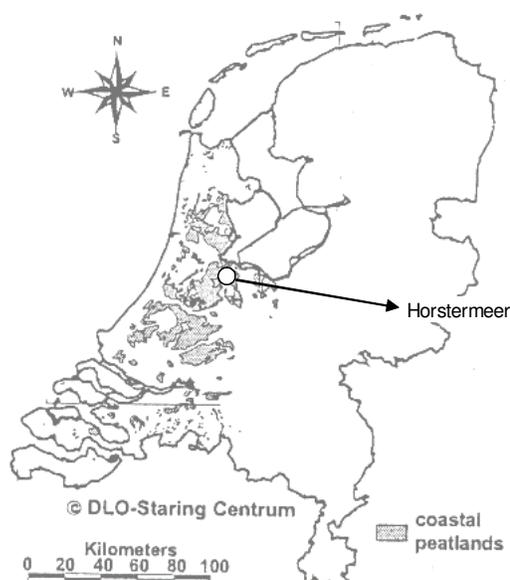

Figure 3.1: Current distribution of peat soils in the western part of the Netherlands (SC-DLO 1992) and location of Horstermeer research site.

Over the last 100 years many peat areas in Europe have been transformed into agricultural land with artificially low water tables. This resulted in an increase of peat oxidation and peat ecosystems have become a strong source of CO₂ (Langeveld et al., 1997). Peat oxidation can be reduced and peat areas can be turned into sinks of CO₂ if water levels are increased as suggested by a host of literature (e.g. Burgerhart, 2001; Van den Bos et al., 2003). In the western part of the Netherlands 10% of the land ($1.6 \cdot 10^3 \text{ km}^2$) consists of peat soils (Fig. 3.1). Currently, most of these soils are managed and have artificially low water tables. Plans exist to convert these agricultural areas into wetland nature by raising the water tables and reducing agricultural use both through

extensification and restoration, depending on the area. This change will probably turn the area from a CO₂-source in a CO₂-sink and alter the emissions of CH₄ and N₂O.

To compile a full GHG balance of a peat land and to understand the mechanisms and processes that affect this balance, comprehensive and long term measurements are needed. All components of that balance should be studied, including the lateral and vertical transport of dissolved carbon and methane out of the system. Currently, only few annual records of CO₂, CH₄ and N₂O measurements in peat lands are available (Regina et al., 2004; Treat et al., 2007 and Alm et al., 1999). Besides, very few comprehensive integrated measurement campaigns have been carried out (Roulet et al., 2007; Soussana, in press 2007; Drösler et al., in press 2007).

This paper describes the full spectrum of GHG's in an abandoned peat meadow area in the western part of the Netherlands which has been transformed from an agricultural area into a wetland nature reserve by raising the water level. Our main goal was to quantify all sinks and sources of GHG's in the area year round and to assess the full GHG balance. This implied, estimating not only the vertical losses and gains through atmosphere, but also vertical and lateral losses of dissolved gases through water and taking into account the different GWP's.

3.2 Site description

The Horstermeer site is located on former agricultural land in a drained natural lake in the central part of the Netherlands (52.144° N, 5.043° E, Fig. 3.1). The research site has been taken out of agricultural production more than 10 years ago, and has developed into semi-natural grassland. The two meter thick soil consists of peat, overlain with organic-rich lake deposits (Table 3.1) and is overlying eolian sands of Pleistocene age. After the site was taken out of agricultural production, the ditch water table has been raised to approximately 10 cm below the land surface. Large parts of the Horstermeer polder are subject to strong groundwater seepage from surrounding lake areas and Pleistocene ice pushed ridges. At the measurement location seepage is largely reduced and even infiltration occurs as a result of the high water table. The surface of the research area consists of 10% of ditches, of 20% of land that is saturated annual (mostly alongside the ditches) and of 70% of relatively dry land with a fluctuating water table (between 0 to 40 cm below the soil surface) and an aerated top-layer. Management consists only of regulation of the ditch water table; no cattle grazing or harvesting takes place, the only removal of vegetation consists of sporadic grazing by roe deer. Vegetation consists of different types of grasses (dominant species *Holcus lanatus*, *Phalaris arundinacea*, *Glyceria fluitans*), horsetail (*Equisetum palustre*, *fluviatile*) reeds (*Phragmites australis*, *Typha latifolia*) and high forbs (*Urtica dioica*, *Cirsium arvense*, *palustre*). Main characteristics of the site are given in Table 3.2.

3.3 Methods and instrumentation

All measurements are carried out over the period 1 January 2004 until 31 December 2006, unless mentioned differently.

Depth (m)	Color	Material	Decomposition	Roots (kg m ⁻³)	pH water	pH (KCl)	Organic matter weight (%)	Permeability (cm day ⁻¹)
0-20	7.5YR2/3	clayey peat	strong	many, 4.1	5.7	5	39.4	4.04

3.3.1 Hydrological measurement techniques, data acquisition and processing

Hydrological measurements included water table recordings of the pressure heads using pressure sensors installed in access tubes in the clayey peat top layer at two locations and in the Pleistocene sand aquifer at one location. Also, the water level in the drainage ditch was measured with a pressure sensor in an access tube. Using the level of the ditch water relative to the height of the overflow weir, discharge could be calculated continuously (Van de Griend, 1989). Water levels were logged on an hourly basis and were all set to the same reference level before further analysis. Outliers and spikes were removed from the dataset. Finally gaps were filled with average values over the surrounding time period. No gaps larger than 24 hours were encountered.

Water samples were taken from the pore water in the clayey peat, the groundwater from the sand aquifer and from the ditch water to determine total carbon (TC) and dissolved CH₄ in the three water types. TC was determined as the sum of total organic carbon (TOC), total inorganic carbon (TIC). Samples were collected using glass filters, installed in the soil or ditch water at 0.2 m depth intervals, and connected to the surface using small diameter Teflon tubes. In the soil these filters were installed in a small diameter borehole, separated from each other by bentonite plugs. The soil filters were installed at three locations, the ditch filters at two locations. Samples were taken using a syringe for drawing up the water, after which the sampling tube was connected to a vacuum exetainer using a three-way stopcock. All sampling was performed anaerobic. TC in the water samples was analyzed with a Dohrmann DC-190 TC analyzer and dissolved CH₄ was analyzed by gas chromatography (Hewlett Packard 5890A, Avondale PA, USA) of the gas-filled headspace of the exetainers. The total CH₄ concentration in the sampled volume was calculated using the gas-water solubility coefficient.

3.3.2 Meteorological measurement techniques, data acquisition and processing

Eddy covariance measurements of CO₂ concentration, water vapour, wind speed and air temperature were performed with a Licor 7500 open path infrared gas analyser (LI-COR Lincoln, NE, USA) and a Windmaster Pro 3 axis Ultrasonic Anemometer (GILL Instruments Limited, Hampshire, UK) directed into the main wind direction. Licor and Anemometer were installed at 4.3 m above the surface. Data were logged digitally on a handheld computer at a rate of 10 Hz (Van der Molen et al., 2006). The EUROFLUX methodology (Aubinet et al., 2000) was applied to the eddy covariance data to calculate the fluxes of momentum, sensible and latent heat and CO₂ on a thirty minute basis. The method of Nakai et al. (2006) was used to apply the angle of attack dependent calibration (Gash and Dolman, 2003; Van der Molen et al., 2004).

Additional micrometeorological measurements were executed at a tower close by the eddy covariance set up. Air pressure was measured (SensorTechnics pressure transducers, model 144SC1216BARO) as well as wet and dry bulb temperatures (Fast response Chromel-Constantan thermocouple with an effective diameter of 0.2 mm, made at the Vrije Universiteit Amsterdam). Incoming and reflected shortwave radiation (Kipp and zonen, Delft, the Netherlands) and longwave radiation (Eppley Pyrgeometers, Eppley laboratory Inc., Model Precision Infrared Radiometers) were measured. As backup of

these radiation balance measurements the net radiation was measured (Campbell Scientific, Q10). All radiometers were installed at a height of 2.5 m (except incoming long wave radiation at 1.6 m height). Wind direction was monitored with a wind vane (Campbell Scientific Ltd, W200P) on top of the tower (4.6 m height) and wind speed with cup anemometers (Vector Instruments model A100M/A100ML) at 3.0 and 2.0 m height. Soil temperature was measured at various depths (0.01, 0.02, 0.04, 0.06, 0.08, 0.10, 0.15, 0.25, 0.40 and 0.60 m) by thermistor probes (Campbell Scientific Ltd, model 107). The canopy skin temperature was measured using infrared thermometers (Everest, model 4000 BL). Precipitation was monitored with a tipping bucket rain gauge (Campbell Scientific Ltd, model ARG100), with a resolution of 0.2 mm, which was installed at 1.05 m above the ground. The instruments were sampled with a data logger (Campbell Scientific, model 23X) every 30 s (2 s for thermocouple) and the data stored as 30 minute averages and standard deviations.

A quality check was performed during which all outliers and unrealistic values were removed from all eddy covariance data and meteorological data (Table 3.3). Next, gap filling with u^* correction was performed through methods that are similar to Falge et al. (2001), with consideration of both the co-variation of fluxes with meteorological variables and the temporal auto-correlation of the fluxes (Reichstein et al., 2005).

variable	unit	minimum value	maximum value
Wind speed (horizontal*vertical) (uw)	[$m^2 s^{-2}$]	-0.10	0.10
Air temperature (T)	[$^{\circ}C$]	-10	50
Carbon dioxide (CO_2) concentration	[ppm]	330	600
Water vapor (H_2O) concentration	[$kg m^{-3}$]	0.002	0.018
Carbon dioxide (CO_2) flux	[$\mu mol m^{-2} s^{-1}$]	-40	30
Sensible heat flux (LE)	[$W m^{-2}$]	-400	1000
Sensible heat flux (H)	[$W m^{-2}$]	-100	300
Incoming and emitted longwave radiation (LW_{in} and LW_{out})	[$W m^{-2}$]	50	700
Incoming and reflected shortwave radiation (SW_{in} and SW_{out})	[$W m^{-2}$]	-50	1200
Air pressure (P_{air})	[kPa]	70	130
Bole temperature (T_{bole})	[$^{\circ}C$]	-40	70

Table 3.3: Ranges of values used in the quality check of the meteorological data.

3.3.3 Soil flux measurement techniques, data acquisition and processing

Closed flux chamber measurements of CH_4 and N_2O fluxes were performed using a Photo Acoustic Field Gas-Monitor (type 1312, Innova AirTech Instruments, Ballerup, Denmark) connected with tubes to closed, dark chambers (non-transparent PVC, 45 x 45 x 12 or 30 cm). The Gas-Monitor detection limit and precision is dependent on the 'least detected level' value of the optical filter used for a specific gas. Reliable measurements could be made from 1.0 ppm for CH_4 and 300 ppb for N_2O with a precision of 2 ppb and 0.6 ppb respectively.

A fan was installed in the chambers to mix the air and increase the representativeness of the measurements. The software of the gas monitor compensates for cross-interference of

CO₂ and water vapour. Additionally, to minimize any possible effect of the interference of those gases, the air was filtered before measurement with a Sodalime filter and a silica gel filter respectively (Van Huissteden et al., 2005). CO₂ and water vapour concentrations remained constant during the flux measurement procedure when the filters were used. The Sodalime filter was replaced when the Gas-Monitor gas monitor indicated concentrations higher than 100 ppm CO₂ while filtering the air for CO₂. The silica gel (Riedel-de Haen, Germany) contains moisture indicating pearls and was replaced at least after every ten measurements or when pearls indicated saturation. To prevent vegetation disturbance, chambers with a height of 30 cm were used. Vegetation was not removed preceding the flux measurements, to maintain the representativeness of the chamber measurements for a larger area. However, when measurements were performed over vegetation higher than 30 cm, it was cut to this size. During each measurement soil temperature and local water table were determined.

On land, at eight fixed locations stainless steel frames with a water-filled gutter were used to seal the chamber from the ambient air during measurement. Six of the locations were positioned in the relatively dry part of the area evenly spread over the various vegetation types. At each of those six locations, fluxes were measured 49 times between January 2004 and December 2006. The two other locations were in the part of the area with saturated soils and were measured 17 times each. On the ditch water surface, measurements were made at two locations. For this purpose a rectangular floater was used allowing the chamber to rest on the water. Between January 2006 and December 2006, fluxes were measured 17 times on the ditch at the east side and 14 times at the ditch at the west side of the research area. At all sites the flux measurements were performed approximately once every 4 weeks during winter and once every two weeks during summer.

For each flux measurement five concentration measurements were performed at two-minute intervals. The series of concentration measurements made with the flux chamber technique were calculated into fluxes by determining linear regression lines from the concentration changes over time. Air pressure and temperature from the moment of measuring were taken into account in the calculations. Data were checked for outliers that may result from instrument error, chamber leakage or irregular ebullition events. Fluxes of N₂O appeared to be negligible small with respect to the GHG balance (between -0.1 and 0.1 mg m⁻² hr⁻¹) and contained measurement errors of more than 70% on average. Therefore, the N₂O flux measurements were not considered in further analyses.

3.3.4 Vegetation and soil analyses

The vegetation was surveyed in 2005 and consisted of vegetation classification and air photo analysis. Biomass was determined in May and October 2005 by harvesting in 40x40 cm squares and separating dead and living biomass. Soil analysis was performed on samples obtained by 0.12 dm³ sample rings for undisturbed sampling. Permeability was determined with a permeameter using the falling head method. The C/N-ratios of these samples were determined with a Flash 122, while the organic matter content was determined with thermogravimetry. Using an automatic oven (Leco TGA-601), samples

were stepwise heated up to 1000°C in an oxygen atmosphere, with heating plateaus at 105°C and 500°C.

3.4 Results

3.4.1 Water balance

Water entered the system either as precipitation or as seeping groundwater, mainly in the ditches. Losses consisted of evapotranspiration and runoff over a fixed weir as well as some infiltration of soil water to the Pleistocene sand aquifer underlying the clayey peat. Since the permeability of the peat layer was very low (0.023 m day^{-1}), we assume that a significant part of the vertical flow in the soil water actually follows sub-horizontal flow paths. Using the precipitation data, water levels and evapotranspiration data (observed by the eddy covariance system) from 25 May 2005 to 25 May 2006, the storage of water per hectare in the soil of the Horstermeer was calculated using the following water balance equation:

$$P - VFD - VFL - Q - ET = \text{Storage} \quad (3.1)$$

, where P is precipitation, VFD is vertical flow in ditches, VFL is vertical flow on land, Q is discharge, ET is evapotranspiration. The annual precipitation was nearly equalled by the evapotranspiration (Table 3.4), but was low compared to the average annual rainfall of 775-800 mm in the area (source: KNMI, Royal Dutch Meteorological Institute). The runoff from the research site consisted only of discharge over the weir and was low. Seepage was the dominant vertical flow in the ditches, while on land infiltration of soil water prevails. Taking into account the relative surface area of land and ditches, the net vertical flow over the whole area was $-0.070 \pm 0.014 \text{ m yr}^{-1}$ (seepage).

waterbalance components	daily average			yearly total		
	(mm day ⁻¹)	uncertainty	(mm day ⁻¹)	(m yr ⁻¹)	uncertainty	(m yr ⁻¹)
Precipitation	-1.85	10%	0.19	-0.676	10%	0.068
<i>Vertical Flow on Land</i>	<i>1.86</i>			<i>0.679</i>		
<i>Vertical Flow at Ditches</i>	<i>-8.40</i>			<i>-3.065</i>		
Net Vertical Flow	-0.19	20%	0.04	-0.070	20%	0.014
Discharge	0.47	10%	0.05	0.173	10%	0.017
Evaporation (land and water)	1.81	10%	0.18	0.660	10%	0.066
Storage	0.24		0.45	0.088		0.165

Table 3.4: Water balance components total per year (right) and averaged per day (left).

3.4.2 Performance of the eddy covariance set-up

Spectral analysis of the fluctuations of the vertical wind speed (w), air temperature (T) and CO_2 in the atmosphere associated with turbulent transport provide a useful tool for assessing the reliability of flux measurements (Stull, 1988; Kaimal and Finnigan, 1994). We determined power-spectra of the wind, temperature and CO_2 concentration as well as

co-spectra of temperature fluxes and CO₂ fluxes (Fig. 3.2). 10 Hz eddy covariance data of seven 30 minute periods in spring 2005 were used for this purpose. The power-spectra and co-spectra were binned and plotted as a function of frequency at log-log scale. Power-spectra for w , T and CO₂ have corresponding slopes showing a proportionality of $-2/3$, which is in agreement with the power law in the inertial sub-range (Eugster and Senn, 1995). Under ideal circumstances the shapes of the $w'CO_2'$ and $w'T'$ co-spectra should be similar. Here the co-spectra showed comparable shapes and have corresponding slopes with a proportionality of $-2/3$. The power spectrum of the CO₂ time series, the co-spectrum of vertical wind and CO₂ as well as the co-spectrum of vertical wind and air temperature indicated that the eddy covariance set-up recorded nearly all the fluctuations in CO₂ associated with turbulent transport (Goulden et al., 1996), and that the measurements were taken in a well established surface layer.

In the energy balance, the ground heat flux (G) in the clayey peat soil was relatively important compared to the latent and sensible heat fluxes (LE and H respectively) and amounted to over half of the energy in the net radiation (R_{net}) (Fig. 3.3). The closure of the energy balance was good (Fig. 3.4), but the values of the sum of LE , H and G were relatively high at sunny days around noon, resulting in a regression line with a slope of more than 1. These high values of the sum of LE , H and G at sunny hours around noon were mainly the result of extremely high apparent G . These high G values were caused by erroneous measurements of the upper soil heat sensors due to overheating during periods with a lot of sunlight. When these data points with erroneous G values were removed from the data set, the regression line had a slope of 0.996 and an R^2 of 0.82. This implied that the quality of the data from the eddy covariance set-up was very good (Lloyd et al., 1997).

The uncertainty of NEE was based on the percentage of data gaps in the eddy covariance data after performing the quality check and u_* -correction. KNMI air temperature data from De Bilt were used to support the gap filling method when necessary. The distance between the site and the KNMI observation is 20 km. Uncertainties resulting from the gap-filling procedure are directly proportional to the amount of gaps filled over the measurement period (Falge et al., 2001). We introduced the maximum error in NEE of 0.675 g C m⁻² per percentage gap-filled per year. The total amount of data gaps was 36.72% for 2004, 26.37% for 2005 and 29.70% for 2006, resulting in a maximum error of 25 g C m⁻² yr⁻¹, 18 g C m⁻² yr⁻¹ and 20 g C m⁻² yr⁻¹ respectively. According to Van der Molen et al. (pers. comm., 2007) the error introduced by the calculation routines was 13% of the total annual NEE.

3.4.3 Carbon dioxide fluxes

The net CO₂ flux followed a daily pattern with periods of net CO₂ uptake during daytime and respiration during nighttime (Fig. 3.3). In Fig. 3.5 the CO₂ fluxes are shown as daily fluxes in g C m⁻² day⁻¹ as well as the cumulative CO₂ flux in g C m⁻² yr⁻¹ over the year. The growing season in 2004 (period where NEE is negative) lasted from 7 April to 14 October and had a NEE of - 543 g C m⁻². The NEE for 2004 was cumulated, resulting in an annual NEE of - 446 ± 83 g C m⁻² yr⁻¹. The growing season in 2005 lasted from 25 March to 8 September and had a NEE - 327 g C m⁻², while the annual NEE amounted -

$311 \pm 58 \text{ g C m}^{-2} \text{ yr}^{-1}$. The growing season in 2006 lasted from 25 April to 2 September and had a NEE of -283 g C m^{-2} , while the annual NEE amounted $-232 \pm 58 \text{ g C m}^{-2} \text{ yr}^{-1}$.

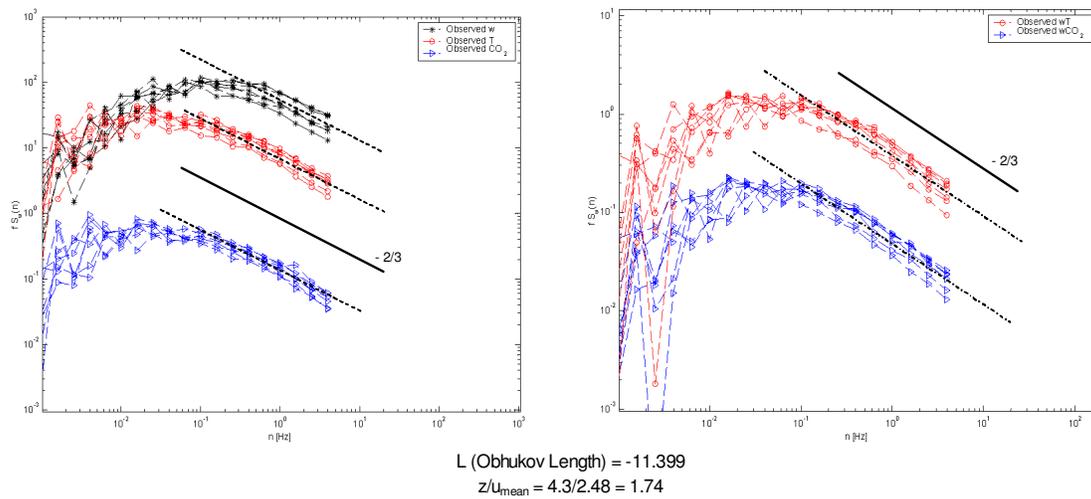

Figure 3.2: Power-spectra of w , T and CO_2 -concentration (left) and co-spectra of $w'T'$ and $w'\text{CO}_2'$ (right) for 10 Hz eddy covariance. Data of seven half hours in spring 2005 are averaged per half hour.

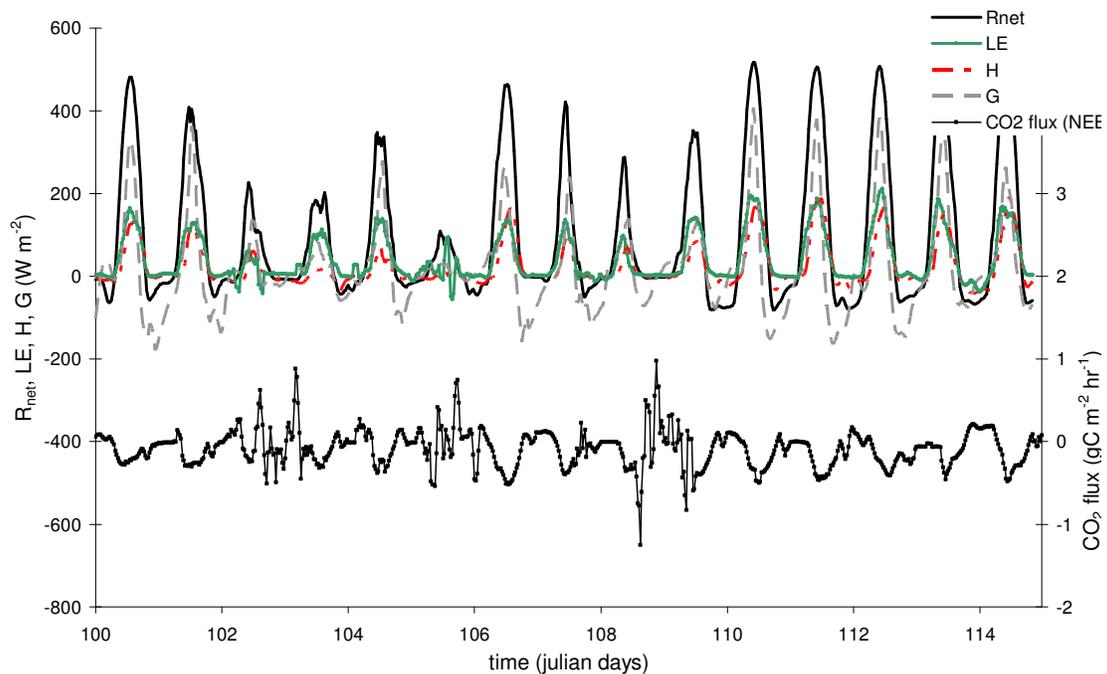

Figure 3.3: Diurnal pattern of energy balance components net radiation, latent heat, sensible heat and ground heat flux and CO_2 flux for seven days in spring 2005.

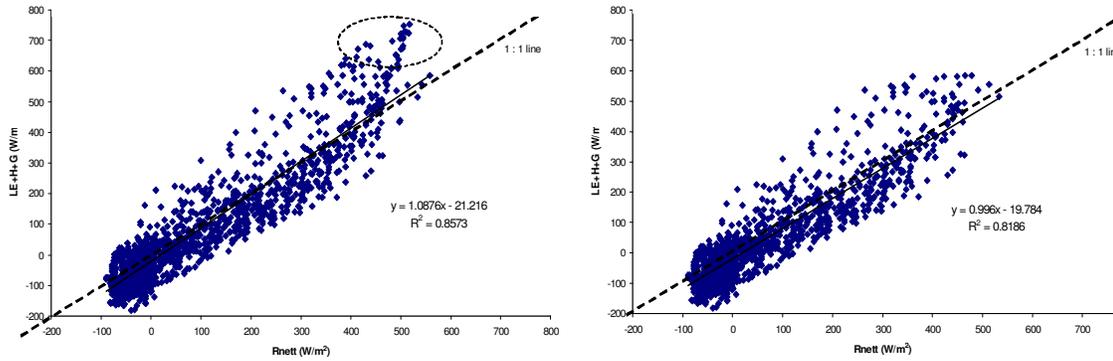

Figure 3.4: Energy balance closure for daytime periods over a three week period during the spring of 2005 with 1:1 line and linear relation. In the left plot a circle is drawn around the outlying mid-day data points. In the right plot mid-day measurements are removed.

Net ecosystem exchange was determined directly from the eddy covariance CO₂ flux measurements and was considered to be the sum of the gross ecosystem production (GEP) and R_{eco} (the sum of heterotrophic and autotrophic respiration). R_{eco} could be expressed by its physical exponential relation with soil temperature (Lloyd and Taylor, 1994; Van't Hoff, 1898). For the Horstermeer site the exponential relation for R_{eco} was determined empirically using nocturnal NEE values (incoming shortwave radiation SW_{in} < 20 W m⁻²) assuming photosynthesis was absent and the NEE consist only of R_{eco} (Fig. 3.6, eq. 3.2).

$$R_{eco} = 0.0077 * e^{(0.1415 * T_{soil})} \quad (\text{error variance} = 0.77 \text{ and } R^2 = 0.5137) \quad (3.2)$$

The results of the flux partitioning of NEE in R_{eco} and GEP are listed in Table 3.5 and plotted over the year (Fig. 3.5). Another attempt to partition the NEE fluxes of 2005 was made by using the model of Reichstein et al. (2005). This model uses air temperature to partition the data and resulted in a partitioning of - 311 g C m⁻² yr⁻¹ NEE in a GEP of - 1135 g C m⁻² yr⁻¹ and R_{eco} of 823 g C m⁻² yr⁻¹. The difference between the results of the two methods for flux partitioning was small. Since the first method (using nocturnal NEE) uses soil temperature instead of air temperature we consider this as a more physically based method as soil temperature was more closely related to R_{eco}.

3.4.4 Methane fluxes

Significantly different fluxes were measured at the three land elements relatively dry land, saturated land and water surfaces and therefore they were considered separately in further analyses and data processing. Measured CH₄ fluxes observed at the relatively dry land varied from -1.1 to 15.2 mg C m⁻² hr⁻¹ with an average of 1.7 ± 0.2 mg C m⁻² hr⁻¹, while fluxes observed at saturated land varied from -8.4 to 48.5 mg C m⁻² hr⁻¹ with a average of 13.8 ± 2.2 mg C m⁻² hr⁻¹. CH₄ fluxes from the ditches varied from 0.4 to 18.4 mg C m⁻² hr⁻¹ with an average of 6.8 ± 0.9 mg C m⁻² hr⁻¹ (Fig. 3.7). The CH₄ fluxes of the saturated land were significantly highest and fluxes from all surface types showed a seasonal trend over the year with the highest fluxes in late spring, summer and early autumn.

	correlation coefficients			n	R ²	statistical parameters			Regression equations

saturated land	0.493	-0.362	-0.671	34	0.243	3.210	0.103	0.292	CH ₄ = exp(2.205 + 0.045*T _{soil})
ditches	0.676	0.000	0.000	31	0.457	9.261	0.011	0.292	CH ₄ = exp(0.767 + 0.079*T _{soil})

Table 3.6: Regression analyses of relations between CH₄ fluxes, soil temperature and water level for relatively dry land, saturated land and ditches. From left to right the correlation coefficients, amount of samples (n) goodness-of-fit of the correlation (R²), F-test with significance (p-value) and variance error as well as the regression equation for CH₄ with soil temperature are shown.

In previous studies relations between soil temperature and CH₄ flux and between soil water level and CH₄ flux were found (Aerts and Toet, 1997; Fiedler and Sommer, 2000; Smith et al., 2003). Statistical analysis of the data showed that in our case the temporal variation of the CH₄ fluxes was significantly correlated with soil temperature, but barely correlated with water level (Table 3.6) while water level is significantly correlated with

soil temperature. This phenomenon was encountered earlier by Wagner et al. (1999) in a marshland. We assume that the lack of correlation between CH₄ flux and soil water level is caused by the soil characteristics at the Horstermeer research site. Peaty and clayey soils often contain anaerobic areas above the water level. In those zones in the soil methanogenesis occurs and CH₄ fluxes at the surface can be higher than expected. As a consequence of the low correlation with CH₄ fluxes, soil water levels were not taken into account in the regression analyses of the CH₄ fluxes. The following exponential regression equations describe the CH₄ flux for the three land elements:

Dry land:

$$\text{CH}_4 \text{ flux} = e^{(-0.261 + 0.060 \cdot T_{\text{soil}})} \quad (\text{error variance} = 1.84 \text{ and } R^2 = 0.086) \quad (3.3)$$

Saturated land:

$$\text{CH}_4 \text{ flux} = e^{(2.205 + 0.045 \cdot T_{\text{soil}})} \quad (\text{error variance} = 0.29 \text{ and } R^2 = 0.243) \quad (3.4)$$

Ditches:

$$\text{CH}_4 \text{ flux} = e^{(0.767 + 0.079 \cdot T_{\text{soil}})} \quad (\text{error variance} = 0.29 \text{ and } R^2 = 0.457) \quad (3.5)$$

Using these regression equations and continuous soil temperature data, the annual CH₄ flux for the three land elements could be determined (Table 3.7 and Fig. 3.8). The CH₄ fluxes of the dry land have a high variance error and were low compared to the fluxes from the ditches and the saturated land. Since uncertainties of the regression equations were very large (Table 3.6), annual totals were also determined using linear interpolation of the data points. Uncertainties were estimated by determination of the total variance between the year totals of the different flux sites. The two methods did not differ significantly both in annual totals and uncertainties (Table 3.7).

3.4.5 Fluxes of Total Carbon and dissolved CH₄ through water

The analyses of soil water, ground water and ditch water for TC and dissolved CH₄ show that highest concentrations were found in the soil water, while the ground water and ditch water contained relatively little TC and dissolved CH₄ (Table 3.8 and Table 3.9). Theoretically, the maximum concentration of dissolved CH₄ in water under the conditions of the soil in the Horstermeerpolder is 26 g C m⁻³ (10°C; 2 m deep). Higher concentrations of CH₄ in the soil water cause a gas pressure that is higher than the hydrostatic pressure and therefore gas bubbles will form in the soil which move upward and will be emitted as gas flux at the soil surface (Obdam et al., 2001; Strack et al., 2006). In further calculations this maximum concentration of 26 g C m⁻³ soil water was used. The fluxes of TC and dissolved CH₄ by water transport were calculated by multiplying the TC and dissolved CH₄ concentrations with the corresponding water volumes from the water balance. Over the year a net amount of 16.069 ± 4.754 g C m⁻² yr⁻¹ was transported out of the research site as TC, while a net amount of 1.182 ± 0.475 g C m⁻² yr⁻¹ was transported out of the research area as dissolved CH₄. This transport mainly took place by infiltration to the groundwater and discharge of surface water.

3.4.6 A full greenhouse gas balance

All incoming and outgoing carbon fluxes through air and water at the measurement site were available for 2005 and were determined per square meter peat meadow per year. As mentioned before, the surface of the research area consists for 10% of ditches, for 20% of land that is saturated year-round and for 70% of land with a fluctuating water table and aerated top-layer. This ratio was taken into account while calculating the annual fluxes of CH₄. Fluxes were considered in amounts of carbon and also converted to their GWP.

The exchange of GHG's through air has a direct effect on the GHG budget of the local atmosphere. The carbon fluxes with water as transport medium form sources and sinks as well, but when and where they will turn into gaseous state and affect the atmospheric GHG balance is unknown. Nevertheless the fluxes through water have an indirect effect on the carbon balance by transporting carbon from the system with the runoff and by transporting carbon into or out of the system via the underground, affecting the availability of carbon in the system for exchange with atmosphere. In order to make this distinction between direct and indirect effects on the carbon balance, the direct net carbon flux with atmosphere was therefore considered separately (Table 3.10), in addition to the total carbon balance where atmosphere and water were both taken into account.

From the total incoming carbon, - 1177 ± 905 g C m⁻² yr⁻¹ (99.5% of all CO₂-equiv.) entered the system due to accumulation of plant material (GEP), while - 3.31 ± 0.80 g C m⁻² yr⁻¹ (0.5% of all CO₂-equivalents) entered the system with groundwater seepage. From the total emitted carbon 866 ± 666 g C m⁻² yr⁻¹ (74.4% of all CO₂-equiv.) left the system through R_{eco}, 31.27 ± 20.43 g C m⁻² yr⁻¹ (23.2% of all CO₂-equiv.) through emission of CH₄ gas, 11.45 ± 2.90 g C m⁻² yr⁻¹ (2.0% of all CO₂-equivalents) through infiltration of soil- and ditchwater to deeper aquifers and 9.11 ± 1.40 g C m⁻² yr⁻¹ (0.8% of all CO₂-equiv.) through discharging ditch water.

When concerning only fluxes with the atmosphere the area was a considerable carbon sink of $-280 \pm 78 \text{ g C m}^{-2} \text{ yr}^{-1}$, while it was a smaller GHG sink given as CO_2 -equiv. of $-182 \text{ g m}^{-2} \text{ yr}^{-1}$ (based on a 100-year time scale) due to the greater GWP of CH_4 . When fluxes through water were added to the balance, the area was a carbon sink of $-262 \pm 84 \text{ g C m}^{-2} \text{ yr}^{-1}$, and only a small net GHG sink given as CO_2 -equiv. of $-71 \text{ g m}^{-2} \text{ yr}^{-1}$ when considered as GWP (Table 3.10).

3.5 Discussion and conclusions

These results show that, with considerable experimental effort, it is possible to estimate a full GHG balance and its uncertainties for a specific area by measuring fluxes of CO₂, CH₄ and N₂O simultaneously, while also paying attention to fluxes of TC and dissolved methane through water and taking into account the different GWP's.

The eddy covariance system performed well, as shown by the power-spectra and co-spectra as well as by the closure of the energy balance, and we can put confidence in those results. NEE was satisfactory partitioned in R_{eco} and GEP using soil temperature and nighttime fluxes for 2004, 2005 and 2006 (Table 3.5 and Fig. 3.5). NEE of CO₂ at the Horstermeer site was high compared to the average NEE of European peat areas which ranges from $-33 \text{ g C m}^{-2} \text{ yr}^{-1}$ (uptake) for undisturbed peat lands to $188 \text{ g C m}^{-2} \text{ yr}^{-1}$ (emission) for drained peat lands (Janssens et al., 2005). The high CO₂-uptake at the site is the result of a combination of the temperate climate, the high water tables and the lack of management. All plant material formed during the long growing seasons (approximately 200 days) can grow to its full size, resulting in a high GEP and remains in situ after dying. The large amounts of respiring plants resulted in high R_{eco} during the summer period, while the anaerobic conditions caused by the high water table are unfavourable for oxidation of organic soils and dead plant material.

CH₄ emissions of the area are the net result of methanogenesis in the anaerobic parts of the soil and CH₄ oxidation in the aerated parts of the soil. A significant difference between CH₄ emissions from relatively dry soils, from saturated soils and from water surfaces was observed (Table 3.7 and Fig. 3.7). Especially the CH₄ fluxes from the ditch water and from the saturated soil bordering the ditches were high. Here, anaerobic processes, including methanogenesis, prevail over aerobic processes as result of the water saturated conditions. These observations suggest even higher CH₄ emissions in the case of a further rise of the water table. Total weighted fluxes result in a relatively high net CH₄ emission ($31.27 \pm 20.40 \text{ g C m}^{-2} \text{ yr}^{-1}$ for 2005 and $32.27 \pm 21.08 \text{ g C m}^{-2} \text{ yr}^{-1}$ for 2006), even compared to the high average fluxes of $11.4 \text{ g C m}^{-2} \text{ yr}^{-1}$ from peat lands in Germany and the Netherlands mentioned by Drösler et al. (in press 2007). The Horstermeer site has relatively high soil water levels, and relatively eutrophic soil conditions. In similar conditions elsewhere also high CH₄ fluxes have been measured (Fiedler and Sommer, 2000). Additionally, in this research the CH₄ fluxes from water surfaces, which increase the average flux from the area, were taken into account. In other research this is often neglected. The emission of CH₄ in the Horstermeer polder accounted for 23.2% of the emitted CO₂-equivalents from the peat meadow site. The uncertainty of the up scaling of CH₄ based only on soil temperature and water level was, however, high. Further research needs to be performed to improve the understanding of methane fluxes.

The history of the Horstermeer site - a recently re-wetted highly productive peat meadow, with nutrients from fertilization still present in the soil - may have influenced the present high CH₄ emission. Nutrient addition may enhance CH₄ emission in peat soils (Aerts and Toet, 1997). The more nutrient-poor peat meadow sites of Van den Pol-Van Dasselaar et al. (1999, 1998a, 1998b), with otherwise comparable soils and water table also exhibit lower fluxes than the Horstermeer site. Fiedler and Sommer (2000) report fluxes of similar magnitude as those from the Horstermeer site, from peaty depressions with strong agricultural influence in southern Germany. At the site, the ditches and their margins produce the highest fluxes, contributing significantly to the GHG budget. The high methane fluxes from ditches also have been reported from other temperate wetland sites. In particular a nutrient-rich pond margin site produced high CH₄ fluxes of up to $77.5 \text{ g C m}^{-2} \text{ yr}^{-1}$ (Van den Pol-Van Dasselaar et al., 1999; Sundh et al., 2000), being a similar hotspot as the ditch margins at the site. Our results therefore also hint towards management options to reduce CH₄ emissions during wetland restoration.

From the undetectable N₂O fluxes, we can draw two conclusions. First, such small fluxes could not be measured properly with the Innova 1312 Gas-Monitor. Second, the N₂O fluxes make a negligible contribution to the GHG balance at the site. The formation of N₂O is normally enhanced by an increase in available mineral nitrogen. Since the site has not been fertilised for more than 10 years, the enhancing effect of fertilisation has probably been diminished and the N₂O emission is reduced to insignificant proportions.

Water, as transport medium of TC and dissolved CH₄, played only a minor role in the balance of GHG's in the area. Only $17.25 \text{ g C m}^{-2} \text{ yr}^{-1}$ of the total CO₂-equivalents were exchanged by transport of water. Although concentrations of TC and dissolved CH₄ in the soil water were high, the impermeable soil prohibits the water to infiltrate quickly. The

groundwater, on the other hand, contains relatively small amounts of TC and dissolved CH₄. Ditchwater and soil water were therefore barely fed with TC and CH₄ through seeping water. Discharge in this controlled area was low compared to other, for example mountainous and uncontrolled areas, where the run off component forms a more important role of washing down of carbon from the system (Hope et al., 2004; Worrall et al., 2005; Ding et al., 2005).

Although the Horstermeer site apparently was a large sink for CO₂ (- 311 g C-CO₂ m⁻² yr⁻¹) and was a considerable carbon sink of - 262 g C m⁻² yr⁻¹ when CH₄ fluxes and transport by water are considered, the area was only a small net GHG sink given as CO₂-equiv. of - 71 g m⁻² yr⁻¹ when considered as GWP. Similar results were found by Friberg et al. (2003) and by Whiting and Chanton (2001). These results show that wetland restoration, for the purpose of restoring wetland habitats and biodiversity, may increase methane emission, but that restored wetlands can become a net sink of GHG's. Additionally, our observations suggest higher CH₄ emissions in the case of a further rise of the water table. Hitherto, the effects of wetland restoration on methane emissions have been poorly quantified, but also other studies indicate an increase of methane emission (Tuittila et al., 2000; Van den Bos et al., 2003).

However, the effect of enhanced methane emission resulting from wetland restoration should be compared with the previous emission of drainage and agricultural use of the soil, with generally lower CO₂-uptake, and extra CO₂ emission from peat decomposition (Van den Bos et al., 2003). Unfortunately we do not have quantitative data from the GHG emissions at the site before the water level was raised. At two similar but drained peat land sites nearby an annual NEE of 157 g C m⁻² yr⁻¹ (emission) and an annual NEE of - 62.4 g C m⁻² yr⁻¹ (uptake) over 2005 was observed (Veenendaal et al., pers. comm., 2007). We have also modelled the CO₂ and CH₄ emission at the site for a 20 cm lower water table than the present water table (approximately the water table position before re-wetting) using the PEATLAND model (Van Huissteden et al., 2006), after calibrating the model for the site using our measurement data of the drier sites. This resulted in an increase of the CO₂ emission from peat degradation of 330 g C m⁻² yr⁻¹, which is 2.36 times the peat decomposition for the present situation. The CH₄ emission from the land surface was reduced by 60% in the model results. The net GHG emission may have been 180% higher at a 20 cm lower water table, mainly by higher soil organic matter decomposition. In this result the effect of carbon export by harvest under agricultural land use in the past, and carbon uptake by vegetation in the present situation is not included. This suggests that although the area is presently only a small GHG sink, it may have been a considerably larger net source before rewetting. It should be noted also that the effects of higher N₂O emission at agricultural land use (Langeveld et al., 1997; Schils et al., 2006) were not considered here.
