Abstract

Background: Right ventricular (RV) diastolic function is impaired in patients with pulmonary arterial hypertension (PAH). Our previous study showed that elevated cardiomyocyte stiffness and myofilament Ca\(^{2+}\)-sensitivity underlie diastolic dysfunction in PAH. This study investigates protein modifications contributing to cellular diastolic dysfunction in PAH.

Methods and Results: RV samples from PAH patients undergoing heart-lung transplantation were compared to non-failing donors (Don). Titin stiffness contribution to RV diastolic dysfunction was determined by Western-blot analyses using antibodies to protein-kinase-A (PKA), Ca (PKCa) and Ca\(^{2+}\)/Calmodulin-dependent-kinase (CamKII) titin and phospholamban (PLN) phosphorylation sites: N2B (Ser469), PEVK (Ser170 and Ser26) and PLN (Thr17) respectively. PKA and PKCa sites were significantly less phosphorylated in PAH compared to donors (p<0.0001). To test the functional relevance of PKA-, PKCa- and CamKII-mediated titin phosphorylation, we measured the stiffness of single RV cardiomyocytes before and after kinase incubation. PKA significantly decreased PAH RV cardiomyocyte diastolic stiffness, PKCa further increased stiffness while CamKII had no major effect. CamKII activation was determined indirectly by measuring PLN Thr17 phosphorylation level. No significant changes were found between the groups. Myofilament Ca\(^{2+}\)-sensitivity is mediated by sarcomeric troponin I (cTnI) phosphorylation. We observed increased unphosphorylated cTnI in PAH compared with donors (p<0.05) and reduced PKA-mediated cTnI phosphorylation (Ser22/23) (p<0.001). Finally, altered in Ca\(^{2+}\)-handling proteins contribute to RV diastolic dysfunction due to insufficient diastolic Ca\(^{2+}\)-clearance. PAH SERCA2a levels and PLN phosphorylation were significantly reduced compared to donors (p<0.05).

Conclusions: Increased titin stiffness, reduced cTnI phosphorylation and altered levels of phosphorylation of Ca\(^{2+}\)-handling proteins contribute to RV diastolic dysfunction in PAH.
Introduction

Patients with pulmonary arterial hypertension (PAH) develop severe right ventricular (RV) failure with impaired diastolic function. In a previous study we showed that collagen deposition, increased cardiomyocyte stiffness and myofilament Ca\(^{2+}\)-sensitivity contribute to compromising RV diastolic function. In the present study we investigate protein changes that underlie RV cardiomyocyte diastolic dysfunction.

Diastolic dysfunction of the left ventricle (LV) was shown to be related to increased cardiomyocyte stiffness as a consequence to functional modifications of the sarcomeric protein titin. By folding during contraction and stretching during relaxation, titin acts as a sarcomeric molecular spring and represents the major determinant of cardiomyocyte stiffness at physiological sarcomere lengths. Titin spans half of the sarcomere, from the Z line to the M band, and consists of a linear array of proximal and distal Ig-like domains, together with N2B and PEVK segments. Its stiffness is modulated by complex mechanisms involving both fast post-translational modification (phosphorylation) and slower changes in isoform expression. The effect of titin phosphorylation depends on the domain targeted. Phosphorylation of the N2B domain has been shown to lower cardiomyocyte stiffness, while PEVK domain phosphorylation exerts the opposite effect.

We have previously shown that, unlike LV diastolic dysfunction, titin isoform composition is not changed in the RV of PAH patients. However, there is an overall decrease in titin phosphorylation in these patients. Therefore, the first aim of this study was to determine the particular titin phosphorylation changes specific to the RV which could explain the increase in RV cardiomyocyte stiffness in PAH patients.

In addition to titin-derived stiffness, RV cardiomyocytes of PAH patients are characterized by increased myofilament Ca\(^{2+}\)-sensitivity, which may in turn influence cardiomyocyte lusitropy. Cardiac Troponin I (cTnI) and cardiac myosin binding protein C (MyBPC) are two important regulators of myofilament Ca\(^{2+}\)-sensitivity. The second aim of this study was to determine whether changes in cTnI and MyBPC phosphorylation are related to the previously observed increase in RV myofilament Ca\(^{2+}\)-sensitivity.

Furthermore, fast cytoplasmic Ca\(^{2+}\)-clearance during diastole is crucial for a normal relaxation pattern. The speed of diastolic Ca\(^{2+}\)-reuptake into the sarcoplasmic reticulum is determined by the activity of the sarcoplasmic reticulum Ca\(^{2+}\)-ATPase-2a (SERCA2a). The rate at which SERCA2a transfers [Ca\(^{2+}\)] across the sarcoplasmic reticulum membrane is enhanced by PKA-mediated phospholamban (PLN) phosphorylation during β-AR stimulation. The inhibitory coupling-protein PLN is removed from SERCA2a secondary to PLN phosphorylation (pPLN). Ca\(^{2+}\)-clearance is also regulated by the sodium-calcium exchanger 1 (NCX1) that is responsible for extracellular extrusion of one Ca\(^{2+}\) ion in exchange for three imported Na\(^{+}\) ions. Previous animal model studies show the relation
between altered Ca\(^{2+}\)-clearance proteins and impaired cardiac relaxation.\(^{14,15}\) However, the expression and function of Ca\(^{2+}\)-clearance proteins in the failing human RV is not known. Therefore, the third aim of this study was to determine whether Ca\(^{2+}\)-clearance protein expression and phosphorylation is altered in the RV of PAH patients. To summarize, the present study investigated the protein changes involved in altering RV cardiomyocyte diastolic function in patients with PAH. Our findings reveal that increased titin stiffness, reduced cTnI phosphorylation and altered expression levels of the Ca\(^{2+}\)-handling proteins contribute to RV diastolic dysfunction in PAH patients.

**Methods**

**Tissue samples**
Explanted RV tissue samples were collected from PAH patients undergoing heart transplantation (n= 11) and compared to RV tissue obtained from non-failing donors (n= 9; Table 1). Human cardiac tissue collection and use by collaborating universities (VU Medical Center, Amsterdam) was approved by the Human Research Ethics Committee of The University of Sydney (AU/1/961515) and the Université Paris-Sud - Inserm U999 (ID RBC 2008-A00485-50). All patients received treatment previous to cardiac transplantation corresponding to the clinical protocols present at the time of the intervention. Various treatments (acute Dobutamine administration) may be associated with the differences observed between patients. After transplantation, RV tissue samples were immediately frozen and stored in liquid nitrogen, preserving the expression and phosphorylation level of the cardiomyocytes.

PAH: pulmonary arterial hypertension. NYHA: New York Heart Association

Titin phosphorylation

To determine kinase-specific titin phosphorylation, donor (n= 7) and PAH (n= 5) frozen RV tissue samples were weighed and pulverized in liquid nitrogen using a mortar and a pestle. Tissue powder was solubilized in 8M urea buffer with DTT and 50% glycerol solution with protease inhibitors (0.16 mmol/L Leupeptin, 0.04 mmol/L E-64 and 0.2 mmol/L PMSF). Samples were loaded on 1% agarose gels stained with Coomassie Blue for protein identification. Equal titin sample dilutions were calculated derived from Myosin Heavy Chain (MHC) protein content and applied for isoform ratio determination.18

Titin phosphorylation of PKA and PKCα sites was assessed using Western blots with specific antibodies against serine 469 (Ser4185, titin N2B cardiac, UnitprotKB: Q8WZ42) on the N2B domain (PKA phosphorylation site) and serine 26 and 170 (Ser11878, UnitprotKB:Q8WZ42 and Ser12022, UnitprotKB:Q8WZ42) on the PEVK domain (PKCα phosphorylation sites). Equal sample loadings were separated on 0.8% agarose gels, transferred to PVDF membranes (Immobilon®-FL, Cat.No.IPFL00010, 045μm) and probed with the relevant antibodies. Membranes were scanned and analyzed using...
Odyssey Infrared Imaging System (Li-COR Biosciences). N2B and N2BA protein content was determined on Ponceau-S-stained membranes and used to normalize for phosphorylation level.5

**RV cardiomyocyte diastolic stiffness**

RV free wall tissue samples (between 20 and 40mg) were defrosted in relaxing solution then sectioned in smaller pieces with a fine dissection scissors. Subsequently, single cardiomyocytes were isolated from these tissue pieces by manual mechanical homogenization. The single cells were then membrane-permeabilized by adding Triton (1%) to the relaxing solution in order to wash out the lipid cellular membranes. The cell solution was repeatedly washed with relaxing solution in order to remove Triton. The cell yield is somewhat variable, depending on the initial amount of tissue, the release of cardiomyocyte from the tissue bulk during mechanical spinning and the loss of cells during Triton washing. Cells for force measurements were chosen based on length and width (length: 50-100μm, width 15-30μm at rest in relaxing solutions).1 A minimum of three cells per sample were used to determine diastolic stiffness and their average was used for further statistical analysis. A single cell was attached with silicone adhesive between a force transducer and a piezoelectric motor. To determine cardiomyocyte stiffness a 25% shortening was performed in the relaxing solution and steady-state stiffness measurements were recorded at increasing sarcomere lengths (1.8 – 2.4 μm).1

Cardiomyocytes were further incubated in relaxing solution with PKA (100U/ml) (Protein Kinase A Catalytic subunit from bovine heart, P2645, Sigma Aldrich) (Donor n= 4, PAH n= 4), CamKδ (50U/ml) or PKC-subunit α (10U/ml) (Protein Kinase C α human isozyme, P1782, Sigma Aldrich) (Donor n= 3, PAH n= 3) at 20 oC for one hour. PKC α also requires Ca2+, therefore the relaxing solution was mixed in a 1:1 concentration ratio with a Ca2+ containing solution of pCa 5.8, obtaining therefore an end pCa of 5.9 in which the cardiomyocytes were incubated. Diastolic stiffness was recorded after PKA, PKCα or CamKδ incubation.19 Individual force values were normalized by the cardiomyocyte cross-sectional area recorded at 2.2 μm sarcomere length.

**Sarcomeric protein phosphorylation**

Sarcomeric protein phosphorylation was determined for each tissue sample (Donor n= 9, PAH n= 11). RV tissue samples were homogenized and separated on gradient gels (NuPAGE® Bis-Tris Gels, Life Technologies). ProQ Diamond Phosphoprotein Stain was used to determine the amount of protein phosphorylation. Gels were further fixed, washed, destained and stained with SYPRO Ruby to determine the total amount of protein. Myofilament protein phosphorylation ratio (ProQ) was calculated relative to the corresponding SYPRO staining (ProQ/SYPRO).20
Cardiac troponin I phosphorylation

Proteins were separated on one-dimensional gel electrophoresis on NuPAGE® Bis-Tris gels (Donor n= 9, PAH= 11). The XCell II Blot Module (Life Technologies) was used for wet protein transfer from mini-gels to ECL membranes (Hybond ECL Nitrocellulose Membrane, GE Healthcare). Blots were incubated with the following primary antibodies against specific protein or protein phosphorylation sites: cTnl dephosphorylated form (4T46, mouse monoclonal antibody, HyTest), cTnl PKA-specific serine 22/23 site phosphorylation (4004, rabbit polyclonal antibody, Cell Signaling Technology). The amount of protein expression or phosphorylation was normalized to the concentration of Ponceau-S stained actin.

The distribution of cTnl phosphorylation (unphosphorylated (P0), mono-phosphorylated (P1), bis-phosphorylated (P2)) was determined on acrylamide Phos-Tag™ gels.

Ca^{2+}-handling proteins expression and phosphorylation

To determine SERCA2a expression, monoclonal rabbit antibody was used (courtesy of Warner S. Simonides, VU University Medical Center, Amsterdam) (Donor n= 9, PAH= 11). PLN binds to and inhibits SERCA2a, while phosphorylation of PLN (pPLN) removes the inhibitory binding of PLN and promotes SERCA2a activity. PLN and pPLN were determined with the following antibodies: total PLN (L15, sc21923, Santa Cruz Biotechnology, Inc), PKA-specific PLN phosphorylation site (Ser16, sc12963, Santa Cruz Biotechnology, Inc) and CaMKIIδ-specific PLN phosphorylation (Thr17, A010-13AP, Badrilla). NCX1 expression was quantified using NCX1-C2C12 antibody (ab2869, Abcam). Cardiac specific Ryanodine Receptor 2 expression was also quantified (C3-33, ThermoFisher Scientific). The amount of protein expression or phosphorylation was normalized to the concentration of Ponceau-S stained actin.

Statistical analyses

Statistical analyses were performed using Prism 5 for Windows (GraphPad Software Inc, San Diego, CA and IBM® SPSS® Statistics 20.0, IBM Corporation, Somers, NY). P-values lower than 0.05 were considered significant. All data are presented as mean ± SEM. Changes in protein expression were tested for significance by a non-paired t-test. Phos-Tag™ analysis was tested for significance by repeated two-way ANOVA followed by the Bonferroni post-hoc test. The effects of PKA, PKCα and CamKIIδ incubation in PAH patients and donors at increasing sarcomere lengths were tested by using a mixed-design ANOVA with disease as between-group measure, sarcomere length and PKA/ PKCα/CamKIIδ-incubation as repeated measures. The green-house Geisser correction was used, because sphericity could not be assumed.
Results

PKA-mediated titin phosphorylation is reduced in PAH RV cardiomyocytes

Cardiomyocyte stiffness is modulated by titin isoform composition and phosphorylation. In our previous study we showed that titin isoform ratio (N2BA/N2B) is not significantly changed in PAH compared to donors (N2BA/N2B\textsubscript{Don}=0.91±0.08, N2BA/N2B\textsubscript{PAH}=0.77±0.07, p=0.20).\(^1\) Therefore, the overall increase in cardiomyocyte stiffness may be a consequence of titin N2B or PEVK domain phosphorylation.

Titin phosphorylation was determined using phospho-specific antibodies for PKA and PKCα phosphorylation sites. We found significantly reduced levels of PKA-dependent phosphorylation of N2B serine 469 site and PKCα-dependent phosphorylation of PEVK serine 170 site (PKA\textsubscript{Don}=1.00±0.03, PKA\textsubscript{PAH}=0.44±0.04, p<0.0001; Figure 1A1) and (PKCα-S170\textsubscript{Don}=1.00±0.06, PKCα-S170\textsubscript{PAH}=0.46±0.06, p<0.0001; Figure 1B1). No significant difference was found in PKCα-dependent phosphorylation of PEVK serine 26 (PKCα-S26\textsubscript{Don}=1.00±0.12, PKCα-S26\textsubscript{PAH}=0.96±0.12, p=0.60; Figure 1B2).

Activation of CamK IIδ determined indirectly by assessing the level of PLN CamK IIδ-dependent phosphorylation of the residue threonine at position 17, which is an exclusive specific site for CamK IIδ.\(^25\) We found no statistical significant difference between the two groups (CamK IIδ\textsubscript{Don}=1.00±0.19, CamK IIδ\textsubscript{PAH}=1.42±0.29, p=0.31; Figure 1C1).

PKA incubation partially restores RV cardiomyocyte stiffness

Subsequently, we tested in a subgroup of samples the functional relevance of reduced titin PKA PKCα and CamK IIδ-mediated phosphorylation. For this purpose, membrane-permeabilized cardiomyocytes in relaxing solution were used to minimize the influence of additional determinants of cardiomyocyte stiffness such as membrane and sarcoplasmic reticulum Ca\(^{2+}\)-handling. Therefore, cardiomyocyte stiffness is attributed solely to the sarcomeric protein titin.

RV cardiomyocyte stiffness was measured at increasing sarcomere lengths, starting at 1.8 μm and stretched to 2.0, 2.2 and 2.4 μm. After PKA incubation we recorded a significant decrease in PAH cardiomyocyte stiffness. Donor cardiomyocyte stiffness was minimally affected by PKA incubation (p\textsubscript{interaction PKA*disease}=0.01; Figure 1A2). PKCα incubation significantly increased cardiomyocyte stiffness in PAH samples and had little effect on donor cardiomyocyte stiffness (p\textsubscript{interaction PKCα*disease}=0.09; Figure 1B3). CamK IIδ incubation decreased cardiomyocyte stiffness of both Don and PAH samples (p\textsubscript{interaction CamK IIδ*disease}= 0.08; Figure1C2) Similar stretch or incubation in relaxing solutions without kinases would not modify baseline cardiomyocyte stiffness.

Reduced phosphorylation of sarcomeric cTnI

Measurements of myofilament Ca\(^{2+}\)-sensitivity revealed a higher sensitivity in PAH compared to donor samples. To investigate whether reduced phosphorylation of the sarcomeric protein cTnI could play a role in determining high myofilament Ca\(^{2+}\)-sensitivity and contribute to RV diastolic dysfunction in PAH, overall sarcomeric protein phosphorylation was determined. A significant decrease in cTnI and MyBPC phosphorylation was found in PAH compared with donors (cTnIDon=1.00±0.15, cTnIPA=0.58±0.11, p=0.03; MyBPCDon=1.00±0.15, MyBPCPA=0.63±0.09, p=0.05; Figure 2). Cardiac troponin T (cTnT) phosphorylation appeared to be higher in PAH compared to donors, however this not statistically significant (cTnTDon=1.00±0.07, cTnTPA=1.29±0.13, p=0.07). No difference was found in desmin phosphorylation (DesminDon=1.00±0.07, DesminPA=0.93±0.06, p = 0.4).

Figure 2: Sarcomeric protein phosphorylation

(C) Example PAH and Donor ProQ and SYPRO protein staining

(A) cTnI phosphorylation. (B) MyBPC phosphorylation. (C) Representative example of donor and PAH phosphorylation. ov= ovalbumin; β= β-casein; MyBPC= myosin binding protein C; cTnT= cardiac troponin T; cTnI= cardiac troponin I; MLC2= myosin light chain; MHC= myosin heavy chain. Data presented as mean ± SEM.
Reduced cTnI phosphorylation was further confirmed by Western blot and Phos-Tag™ analyses. The amount of dephosphorylated cTnI was significantly higher in PAH compared to donors (dephos-cTnI<sub>Don</sub>=1.00±0.17, dephos-cTnI<sub>PAH</sub>=1.67±0.17, p=0.01; Figure 3A). The cTnI PKA specific phosphorylation site (serine 22/23) showed significantly lower phosphorylation in PAH samples compared with donors (cTnI-S22/23<sub>Don</sub>=1.00±0.08, cTnI-S22/23<sub>PAH</sub>=0.41±0.11, p= 0.0004; Figure 3B).

Phos-Tag™ analysis demonstrated that the distribution of cTnI phosphorylation (unphosphorylated (P<sub>0</sub>), mono-phosphorylated (P<sub>1</sub>), and bis-phosphorylated (P<sub>2</sub>) in PAH-cardiomyocytes was shifted to more unphosphorylated cTnI in comparison to donors, evident from higher levels of unphosphorylated cTnI and lower levels of bis-phosphorylated cTnI (P<sub>Don</sub>0/1/2=38.38±11.55% / 20.78±3.57% / 40.84±14.21%, P<sub>PAH</sub>0/1/2=67.28±5.86%,/ 21.55±3.12% / 11.17±3.69%, p interaction = 0.008; Figure 3C).

Altered expression of Ca<sup>2+</sup>-handling proteins

SERCA2a expression was significantly lower in PAH cardiomyocytes (SERCA2a<sub>Don</sub>=1.00±0.14, SERCA2a<sub>PAH</sub>=0.56±0.09, p= 0.02; Figure 4A). Total PLN protein levels
were higher in PAH, however the difference failed to reach statistical significance (PLN\textsubscript{Don}=1.00±0.13, PLN\textsubscript{PAH}=2.44±0.65, p= 0.23; Figure 4B). PLN phosphorylation was determined as a ratio calculated from total PLN protein level in relation to the amount of phosphorylated PLN. pPLN was significantly lower in PAH compared with donors (pPLN/PLN\textsubscript{Don}=1.00±0.12, pPLN/PLN\textsubscript{PAH}=0.55±0.10, p= 0.02; Figure 4C). The inhibitory effect of PLN on SERCA2a was determined by the PLN/SERCA2a ratio, which was higher in PAH compared with donors (PLN/SERCA2a\textsubscript{Don}=1.5±0.47, PLN/SERCA2a\textsubscript{PAH}=5.71±1.67, p=0.19; Figure 4D). In addition, the lower level of NCX1 protein level in PAH was not statistically significant (NCX1\textsubscript{Don}=1.00±0.28, NCX1\textsubscript{PAH}=0.55±0.12, p= 0.36; Figure 4E). The expression level of RyR2, responsible for systolic Ca\textsuperscript{2+} release from the sarcoplasmic reticulum was not significantly different in the two groups (RyR\textsubscript{2Don}=1.00±0.05, RyR\textsubscript{2PAH}=1.26±0.13, p= 0.11; Figure 4F).

**Figure 4: Ca\textsuperscript{2+} handling proteins expression and phosphorylation**

Discussion

This study demonstrates that cellular RV diastolic function in PAH is altered as a consequence of:
1. Reduced PKA-mediated titin phosphorylation resulting in increased RV cardiomyocyte stiffness.
2. Decreased cTnl phosphorylation, increasing Ca\(^{2+}\)-sensitivity.
3. Decreased levels of SERCA2a and PLN phosphorylation, suggesting reduced diastolic Ca\(^{2+}\)-clearance.

Titin determined cardiomyocyte stiffness

This is the first human study to show altered titin phosphorylation and its functional consequence in the failing right ventricle. We demonstrate that in RV tissue from PAH patients, titin serine 469 (PKA site) and serine 170 (PKCa site) phosphorylation are significantly reduced. No change was observed in titin serine 26 (PKCa site) phosphorylation between PAH and donor. Interestingly, these findings differ from those previously observed in LV pressure overload animal models. Hudson et al. investigated titin phosphorylation in a mouse model of hypertensive left heart failure induced by transverse aortic constriction. They concluded that increased PKCa-mediated phosphorylation of serine 26 in the PEVK domain was the main contributor to left ventricular cardiomyocyte stiffness. No significant change in PKA-mediated phosphorylation of the N2B domain was found in this animal model of left heart failure. Kötter et al. used end-stage human LV tissue obtained during heart transplantation from hypertrophic cardiomyopathy (HCM) and idiopathic dilated cardiomyopathy (iDCM) patients and concluded that the significant increase in PEVK domain serine 26 (PKCa site) phosphorylation, together with altered titin N2B domain phosphorylation, determine the increase cardiomyocyte stiffness in LV failure. This suggest that while in LV failure PKCa-dependent hyperphosphorylation of titin PEVK domain serine 26 plays a key role in increasing stiffness, in RV failure secondary to pressure overload, PKA-dependent hypophosphorylation of N2B domain serine 469 in central in increasing cardiomyocyte stiffness.

To demonstrate the functional relevance of altered serine 469 and serine 170 phosphorylation, we incubated RV cardiomyocytes with the catalytic subunits of PKA and PKCa and measured the effects on RV cardiomyocyte stiffness. We observed that PKA incubation lowered stiffness only in PAH and largely restored RV cardiomyocyte stiffness to values observed in donors. In contrast, PKCa incubation increased cardiomyocyte stiffness in both PAH but far less in donor. At sarcomere lengths longer than physiological (>2.2μm), PKCa incubation resulted in a large increase in RV cardiomyocyte stiffness in PAH patients. These findings suggest that titin serine 469 (PKA site) hypophosphorylation is the main contributor to RV diastolic stiffness in PAH, rather than titin serine 170...
(PKCα site) hypophosphorylation. The latter may be a compensatory mechanism to prevent further increase in titin stiffness in RV cardiomyocytes in PAH patients. In addition to PKA-, PKCa- and CaMKδI-dependent phosphorylation, titin stiffness is subject to the fine tuning of a number of different kinases with opposite or complementary effects. In humans, protein kinase G (PKG) was shown to phosphorylate N2B serine 469 with same functional effect as PKA. In addition to PKA and PKG, recent data show that extracellular-signal-regulated kinase 2 (ERK2) can decrease titin stiffness. However, the phosphorylation site is still to be resolved. Furthermore CaMKIIδ was shown to phosphorylate N2B (other sites than PKA) and PEVK domains and overlap with PKCa phosphorylation sites on the PEVK domain. However, the functional role of these novel phosphorylation pathways was not yet shown in human.

**cTnI modulated Ca²⁺-sensitivity**

An increase in sarcomere Ca²⁺-sensitivity can lead to incomplete actin-myosin detachment, despite low [Ca²⁺] levels, impairing the relaxation phase. Previously it was demonstrated that sarcomeric protein phosphorylation plays an important role in determining Ca²⁺-sensitivity. In our study, we observed reduced cTnI and MyBPC phosphorylation. Site-specific analysis further revealed that PKA-mediated cTnI phosphorylation of serine 22/23 was less phosphorylated in PAH. This was further confirmed by Phos-Tag™ analyses showing a higher level of unphosphorylated (P0) cTnI and reduced level of bisphosphorylated (P2) cTnI. Although in our previous study only a small increase in Ca²⁺-sensitivity was observed, this could further contribute to the RV diastolic impairment in PAH patients.

**Diastolic Ca²⁺-clearance**

For proper cardiomyocyte relaxation, cytosolic [Ca²⁺] must promptly drop, followed by myofilament detachment and sarcomere elongation to diastolic length. Therefore, perturbations in diastolic Ca²⁺-clearance are central to the development of diastolic dysfunction. Substantial decrease in SERCA2a protein levels and PKA-mediated PLN phosphorylation would imply that cellular relaxation pattern is altered in PAH patients, due to increased residual diastolic [Ca²⁺]. However, the actual correlation between altered protein expression or phosphorylation and their functional relevance could not be determined in the present study.

**PAH and excessive neurohormonal activation**

Although the three mechanisms discussed here clearly affect diastolic function in a distinct way and therefore may have different relevance *in vivo*, we observe a common factor to all three mechanisms: reduced PKA-mediated phosphorylation. Decreased PKA phosphorylation determined increased titin-derived RV cardiomyocyte stiffness,
increased myofilament cTnI dependent Ca$^{2+}$-sensitivity and altered Ca$^{2+}$-clearance due to reduced PLN phosphorylation. In the setting of heart failure, disturbed PKA phosphorylation is attributed to impaired β-AR signaling as a consequence of increased neurohormonal stimulation and compensatory receptor β-AR downregulation. In PAH, however, the consequences of increased neurohormonal activation are less well understood. Bristow et al. observed decreased β-AR density in failing RV myocardium. In addition, reducing neurohormonal activity in an experimental model of PAH resulted in improved RV diastolic function and partially restored sarcomeric protein phosphorylation (cTnI and cMyBPC). Therefore, we propose that in PAH patients the reduced PKA-mediated phosphorylation of titin, cTnI and PLN are at least partially caused by increased neurohormonal activation.

**Clinical implications**

Beta-blocker therapy is known to counteract the loss of function of β-AR signaling by restoring β-AR density, followed by the restoration of PKA-mediated phosphorylation. In a previous experimental PAH model, rats receiving beta-blocker therapy showed a significant reduction in RV diastolic stiffness and increase in cTnI and cMyBPC phosphorylation compared with PAH rats receiving placebo. These effects are likely due to reduced neurohormonal activation in PAH rats receiving beta-blockers, normalization of β-adrenergic stimulation and increased PKA-mediated titin, cTnI and MyBPC phosphorylation. Although well tolerated in PAH rats, beta-blockers are currently not recommended in PAH due to possible negative inotropic effects. Nevertheless, based on the beneficial effects of beta-blockers in PAH experimental models, we have initiated a phase II clinical study to investigate the safety and efficacy of beta-blocker (Bisoprolol) in patients with PAH (Clinicaltrails.gov identifier: NCT01246037). The future results of this study will reveal whether indeed, β-AR /PKA signaling pathway is a novel therapeutic target for RV diastolic impairment in PAH patients.

**Limitations**

Efficient diastolic Ca$^{2+}$-clearance is vital for ensuring proper relaxation for the sarcomere, therefore in this study we quantified the expression level of the most important proteins involved in Ca$^{2+}$-handling. However, the functional relevance of these changes was not assessed. Functional relevance can only be determined in freshly harvested myocardial tissue/ whole hearts, usually from animal models where changes in protein levels are consequently related to the functional data. In our study we used human myocardial tissue preserved by freezing, which did not alter the protein level and phosphorylation status, however made functional assessments impossible. Nevertheless, previous animal model studies show a clear relation between expression levels and function of Ca$^{2+}$-handling proteins, therefore we speculate that this is also the case in our study.
There are several other mechanisms which regulate diastolic dysfunction such as: increased radical oxygen species production, T-tubules loss or disorganization of cardiomyocyte cytoarchitecture. Although important for diastolic function, this study only focused on the cardiomyocyte stiffness, myofilament Ca$^{2+}$-sensitivity and altered Ca$^{2+}$-clearance protein levels.\textsuperscript{34}

**Conclusions**

The present study provides novel insight in the molecular mechanism underlying RV diastolic impairment in patients with PAH. We observed that reduced PKA-mediated phosphorylation of the giant sarcomeric protein titin contributed significantly to RV cardiomyocyte stiffness. In addition, phosphorylation of the sarcomeric protein cTnI was significantly reduced in PAH. Finally, reduced PLN phosphorylation and SERCA2a protein levels may indicate altered diastolic Ca$^{2+}$-clearance.

**Funding sources**

Frances S. de Man, Coen Ottenheijm, Jolanda van der Velden and Anton Vonk-Noordegraaf were supported by a VENI (916.14.099) and VIDI (917.12.319; 917.11.344; 917.96.306) grant from the Dutch Foundation for Scientific Research. Silvia Rain and Anton Vonk-Noordegraaf were supported by The Netherlands organization for Health Research and Development (ZonMw 95110079). Silvia Rain was supported by the European Society of Cardiology “First initiative travel grant”. Harm-Jan Bogaard was supported by the National Institute of Health (NIH HL062881). Denielli Bos and M. Louis Handoko were supported by Science Without Borders grant, CNPq Brasil.
