Chapter 6

Salivary and serum cortisol and relation to blood pressure in infancy and early childhood in very-low-birth-weight infants

Miranda de Jong, Anneke Cranendonk, Mirjam M. van Weissenbruch

ABSTRACT

Background
Programming of the hypothalamic-pituitary-adrenal (HPA) axis possibly explains the relation between intra-uterine growth restriction (IUGR) and/or preterm birth and elevated blood pressure in later life. Very-low-birth-weight infants (birth weight < 1500 g) have high prevalence of raised blood pressure, already in early childhood. We investigated cortisol levels, relation to blood pressure and reliability of salivary cortisol in infancy and early childhood in very-low-birth-weight infants.

Methods
We included 41 children, participating in the randomized controlled Neonatal Insulin Replacement Therapy in Europe (NIRTURE) trial. Serum and salivary samples for cortisol measurement (immunoassay) were taken simultaneously at 6 months and separately at 2 years corrected age. Blood pressure was measured at 2 years corrected age.

Results
Serum cortisol was significantly correlated to systolic and diastolic blood pressure in boys and in the early-insulin treated group. At 2 years corrected age, serum cortisol was significantly higher in the early-insulin group compared to the standard care group. At 6 months corrected age, salivary cortisol was significantly correlated to serum cortisol.

Conclusions
In very-low-birth-weight boys, the positive correlation between cortisol and blood pressure is present at 2 years corrected age. Early insulin therapy could affect programming of the HPA axis. Salivary cortisol mirrors serum levels at 6 months corrected age.
INTRODUCTION

The inverse relation between birth weight and blood pressure, and consequently the importance of fetal growth for later blood pressure, was first indicated by Barker et al. (1, 2) and confirmed in many studies in children and adults, reviewed by Huxley et al. (3). Preterm born infants have impaired growth in early postnatal life, in a period comparable to the third trimester of pregnancy, and also have a higher blood pressure in later life (4).

One of the proposed mechanisms underlying the association between intra-uterine growth restriction (IUGR) and/or preterm birth and blood pressure is programming of the hypothalamic-pituitary-adrenal (HPA) axis. In adults, birth weight is inversely associated with cortisol levels and cortisol levels are positively correlated to blood pressure (5, 6). This was also shown in children between the ages of 4.9 and 15.5 years and born at a gestational age > 32 weeks (7). In preterm born young adult men, cortisol is also associated with high systolic blood pressure (8). There are no data about the association between cortisol and blood pressure in preterm born infants < 32 weeks in early childhood. We recently showed that at the corrected age of 2 years, very-low-birth-weight (VLBW) infants (birth weight < 1500 g) have a high prevalence of raised blood pressure (systolic and/or diastolic ≥ 90th percentile for age, sex and height) (9). Elevated blood pressure (compared to published reference standards) in early childhood in VLBW infants was also reported by Duncan et al. (10).

The aim of the present study was to measure cortisol levels in VLBW infants at 6 months and 2 years corrected age and correlate cortisol levels at 2 years corrected age to blood pressure. Our second aim was to investigate the reliability of salivary cortisol measurements in this population. As the subjects were part of the Neonatal Insulin Replacement Therapy in Europe (NIRTURE) trial, our third aim was to evaluate the effect of early insulin therapy on salivary and serum cortisol levels at 6 months and 2 years corrected age. The blood pressure values were presented earlier, as part of the evaluation of all the metabolic syndrome components in this population (9). However, the emphasis of the present study is on cortisol, programming of the HPA axis and cortisol measurement in saliva compared to serum.

METHODS

Study population
The subjects were part of the NIRTURE trial, an international multicenter randomized controlled trial investigating the role of early insulin therapy in VLBW infants (11). After written informed consent was obtained from the parents, VLBW infants younger than 24 hours of age and requiring intensive care were randomized to receive continuous intra-
venous infusion of insulin for the first 7 days of life or standard neonatal care with insulin treatment only in case of hyperglycemia. Exclusion criteria included maternal diabetes and major congenital anomalies. All 47 infants participating in the NIRTURE trial in our neonatal intensive care unit were eligible for the present study. Therefore the sample size of the present study was determined by the number of infants we included in the NIRTURE trial. After discharge, all 42 surviving infants were followed in the outpatient clinic with visits at expected date of delivery and at the corrected ages of 3 months, 6 months, 1 year and 2 years. Approval from the ethics committee of the VU University Medical Center was obtained.

Data collection
At every visit to the outpatient clinic, body weight was measured using an electronic scale to the nearest 0.1 kg, length and head circumference were measured to the nearest 0.1 cm and BMI was calculated. Standard deviation scores (SDS) of weight, length and BMI were calculated according to Dutch references (12, 13). At 2 years corrected age, blood pressure was measured in the calm state using an appropriately sized cuff and automated blood pressure measuring device (Dinamap, Critikon, Tampa, Florida, USA); the mean value of two measurements was used for analysis and measurements in noncalm state were excluded. At 6 months and 2 years corrected age, blood and salivary samples were taken for measurement of cortisol. We only took blood samples at two of the visits to the outpatient clinic to limit the burden of blood sampling for the children. Saliva was collected by suction using a saliva aspiration set. At 6 months corrected age, this was performed by the research nurse in the outpatient clinic early in the afternoon and just before the blood sample was taken. At 2 years corrected age, saliva was collected by the parents at home immediately after awakening in the morning; the blood sample was taken early in the afternoon. As the saliva sample at 2 years corrected age was the only sample taken in the morning, comparison of 2-year salivary cortisol to the other cortisol values, all taken in the afternoon, was not possible.

Assays
Serum cortisol was measured by competitive immunoassay (Advia Centaur, Siemens Medical Solutions Diagnostics, Malvern, Pennsylvania, USA). Lower limit of quantitation is 30 nmol/l, intra-assay coefficient of variation is 3% at 700 nmol/l and inter-assay coefficients of variation are 6% at both 150 nmol/l and 500 nmol/l and 8% at 1000 nmol/l.

Salivary cortisol was measured by automated immunoassay (Architect i2000, Abbott, North Chicago, Illinois, USA). This assay is described in detail by Heijboer et al. (14).
Statistical analysis

Statistical analyses were performed using the Statistical Package of Social Sciences software for Microsoft Windows version 19 (SPSS Inc., Chicago, Illinois, USA). Differences between subgroups were evaluated using Student’s t-test for normally distributed values and Mann-Whitney test and Wilcoxon signed-rank test for not normally distributed values. Bivariate correlation analysis was performed to study the relations between birth weight, cortisol concentrations and blood pressure and between serum and salivary cortisol concentrations. P values < 0.05 were considered as significant.

RESULTS

In our neonatal intensive care unit, 47 VLBW infants participated in the NIRTURE trial. Five infants died. One child was excluded because parents refused blood and salivary sampling at 6 months corrected age; at 2 years corrected age this child was lost to follow-up. Forty-one children were included in the present study. Table 1 shows the characteristics and outcome of these children. Seventeen infants (9 male/8 female) were assigned to the early-insulin group and 24 infants (12 male/12 female) received standard neonatal care. In the standard care group, 6 infants were treated with insulin for 1 or 2 days because of hyperglycemia due to sepsis.

aStandard deviation scores (SDS) at birth according to Niklasson et al. (15).
bSmall-for-gestational-age (SGA) was defined as a birth weight below the 10th percentile.
cHighest level of education completed by either parent was used as an indicator of socioeconomic status and classified as low (primary school, low occupational training), medium (high school, medium occupational training) or high (high occupational training, university).
dBronchopulmonary dysplasia was defined as the need for supplemental oxygen at 36 weeks postmenstrual age.
Table 2 shows serum and salivary cortisol at 6 months and 2 years corrected age and blood pressure at 2 years corrected age with the group divided in male and female children and divided in early-insulin therapy and standard care. At 2 years corrected age, serum cortisol was significantly higher in children treated with insulin compared to children in the standard care group. Paired-samples t-test showed no differences between serum cortisol levels at 6 months and 2 years corrected age (both taken in the afternoon).

All data are expressed as median and range. The total group of VLBW children (n = 41) is divided in boys and girls and divided in treatment group (standard care and early-insulin therapy). Marked data are significantly different.

* sample taken in the afternoon.

b sample taken in the morning.

c cortisol serum at 2 years corrected age: standard care vs. early-insulin p = 0.002 (Mann-Whitney test).

At 2 years corrected age, serum cortisol (taken at the visit to the outpatient clinic early in the afternoon) was significantly correlated to both systolic blood pressure and diastolic blood pressure in boys ($r = 0.79; p < 0.001$ and $r = 0.65; p = 0.004$ resp.), but not in girls ($r = 0.39; p = 0.15$ and $r = 0.47; p = 0.08$ resp.) and in the early-insulin group ($r = 0.80; p = 0.001$ and $r = 0.68; p = 0.008$ resp.), but not in the standard care group ($r = 0.33; p = 0.19$ and $r = 0.36; p = 0.14$ resp.). These correlations are shown in Figure 1. There was no correlation between salivary cortisol (taken at home early in the morning) and blood pressure. Birth weight was not correlated to serum or salivary cortisol at any age or to blood pressure at 2 years corrected age. At 6 months corrected age, salivary cortisol was significantly correlated to serum cortisol ($r = 0.62; p = 0.001$).
The present study shows that in subgroups of VLBW infants, the positive correlation between cortisol and blood pressure can be demonstrated as early as at 2 years corrected age. At 2 years corrected age, insulin-treated children have higher serum cortisol levels than children in the standard care group. Salivary cortisol measurement is reliable in 6-month-old VLBW children.

The positive correlation between serum cortisol levels and blood pressure has been shown before in adults and older children (5-7). The present study confirms this association in early childhood in VLBW infants and supports the hypothesis that programming of the HPA axis may contribute to the high prevalence of raised blood pressure in this population (9, 10). The correlation between cortisol and both systolic and diastolic blood pressure was significant only in boys. This is in accordance with the study of Szathmari et al. (8) in preterm born young adults, showing an association between cortisol and high systolic blood pressure only in men. In older children (between the ages of 4.9 and 15.5
years), including preterm born children > 32 weeks gestation, the association between cortisol levels and blood pressure was not different between boys and girls (7). The age groups, which show the sex difference in this association (adulthood and early childhood), correspond to periods that the hypothalamic-pituitary-gonadal axis is active, as this is also active in the postnatal period (16, 17).

VLBW children treated with insulin in the first postnatal week, have higher serum cortisol levels at 2 years corrected age than children treated with standard care. In the insulin treated group, there also was a significant correlation between serum cortisol levels and blood pressure (systolic and diastolic). These results suggest that early insulin treatment may affect the programming of the HPA axis, although the study population was small. Animal studies in offspring of diabetic mothers show that increased insulin concentrations within the immature hypothalamus may lead to irreversible malprogramming (with morphological changes) of regulation centres for metabolism and body weight (18).

Proposed mechanisms for the positive relation between increased HPA axis activity and blood pressure are reduced insulin sensitivity and activation of the central sympathetic nervous system (19). The absence of a significant correlation between salivary cortisol and blood pressure at 2 years corrected age could be caused by the small population of our study. On the other hand, the fact that only afternoon (serum) and not morning (salivary) cortisol levels were correlated to blood pressure, could also indicate that the failure to suppress cortisol during the day, resulting in sustained hypercortisolism, is related to elevated blood pressure.

In this study, we found a significant correlation between salivary and serum cortisol levels in VLBW infants at 6 months corrected age. This finding confirms the reliability of salivary cortisol measurements shown before in premature infants (20) and older children (21). We did not find the inverse relation between birth weight and cortisol levels as shown in other studies in children (7, 22).

Our study is limited by the small number of infants and the lack of data from term born children. The correlations between cortisol and blood pressure need to be confirmed in a larger group of VLBW infants. Cortisol levels and blood pressure have to be compared with those of term born children from our own population.

In conclusion, in VLBW boys, the positive correlation between cortisol and blood pressure is already present at 2 years corrected age, suggesting that programming of the HPA axis could contribute to the high prevalence of raised blood pressure in VLBW infants in early childhood. Early insulin treatment could affect this programming, resulting in higher cortisol levels. Salivary cortisol mirrors serum levels at 6 months corrected age and has an important advantage as non-invasive method, especially in children.
